and certain drugs. Neutrophils from newborn infants have abnormal adherence, chemotaxis, and bactericidal activity. Cells from patients with thermal injury, trauma, and overwhelming infection have defects in cell motility and bactericidal activity similar to those seen in neonates.

**Clinical Findings**

Recurrent bacterial or fungal infections are the hallmark of neutrophil dysfunction. Although patients will have infection-free periods, episodes of pneumonia, sinusitis, cellulitis, cutaneous and mucosal infections (including perianal or peritonsillar abscesses), and lymphadenitis are frequent. As with neutropenia, aphthous ulcers of mucous membranes, severe gingivitis, and periodontal disease are also major complications. In general, S aureus or gram-negative organisms are commonly isolated from infected sites; other organisms may be specifically associated with a defined neutrophil function defect. In some disorders, fungi account for an increasing number of infections. Deep or generalized infections, such as osteomyelitis, liver abscesses, sepsis, meningitis, and necrotic or gangrenous soft-tissue lesions, occur in specific syndromes (eg, leukocyte adherence deficiency or chronic granulomatous disease). Patients with severe neutrophil dysfunction may die in childhood from severe infections or associated complications. Table 30–6 summarizes pertinent laboratory findings.

**Treatment**

The mainstays of management of these disorders are anticipation of infections and aggressive attempts to identify the foci and the causative agents. Surgical procedures to achieve these goals may be both diagnostic and therapeutic. Broad-spectrum antibiotics covering the range of possible organisms should be initiated without delay, switching to specific antimicrobial agents when the microbiologic diagnosis is made. When infections are unresponsive or they recur, granulocyte transfusions may be helpful.

Chronic management may include prophylactic antibiotics. Trimethoprim-sulfamethoxazole and some other antibiotics (eg, rifampin) enhance the bactericidal activity of neutrophils from patients with chronic granulomatous disease. Some patients with Chédiak-Higashi syndrome improve clinically when given ascorbic acid. Recombinant γ-interferon decreases the number and severity of infections in patients with chronic granulomatous disease. Demonstration of this activity with one patient group raises the possibility that cytokines, growth factors, and other biologic response modifiers may be helpful in other conditions in preventing recurrent infections. Bone marrow transplant has been attempted in most major congenital neutrophil dysfunction syndromes, and reconstitution with normal cells and cell function has been documented. Combining genetic engineering with autologous bone marrow transplant may provide a future strategy for curing these disorders.

**Prognosis**

For mild to moderate defects, anticipation and conservative medical management ensure a reasonable outlook. For severe defects, excessive morbidity and significant mortality still exist. In some diseases, the development of noninfectious complications, such as the lymphoproliferative phase of Chédiak-Higashi syndrome or inflammatory syndromes in chronic granulomatous disease, may influence prognosis.

---

**LYMPHOCYTOSIS**

From the first week up to the fifth year of life, lymphocytes are the most numerous leukocytes in human blood. The ratio then reverses gradually to reach the adult pattern of neutrophil predominance. An absolute lymphocytosis in childhood is associated with acute or chronic viral infections, pertussis, syphilis, tuberculosis, and hyperthyroidism. Other noninfectious conditions, drugs, and hypersensitivity and serum sickness–like reactions cause lymphocytosis.

Fever, upper respiratory symptoms, gastrointestinal complaints, and rashes are clues in distinguishing infectious from noninfectious causes. The presence of enlarged liver, spleen, or lymph nodes is crucial to the differential diagnosis, which includes acute leukemia and lymphoma. Most cases of infectious mononucleosis are associated with hepatosplenomegaly or adenopathy. The absence of anemia and thrombocytopenia helps to differentiate these disorders. Evaluation of the morphology of lymphocytes on peripheral blood smear is crucial. Infectious causes, particularly infectious mononucleosis, are associated with atypical features in the lymphocytes, such as basophilic cytoplasm, vacuoles, finer and less-dense chromatin, and an indented nucleus. These features are distinct from the characteristic morphology associated with lymphoblastic leukemia. Lymphocytosis in
childhood is most commonly associated with infections and resolves with recovery from the primary disease.

**EOSINOPHILIA**

Eosinophilia in infants and children is an absolute eosinophil count greater than 300/μL. Marrow eosinophil production is stimulated by the cytokine IL-5. Allergies, particularly those associated with asthma and eczema, are the most common primary causes of eosinophilia in children. Eosinophilia also occurs in drug reactions, with tumors (Hodgkin and non-Hodgkin lymphomas and brain tumors), and with immunodeficiency and histiocytosis syndromes. Increased eosinophil counts are a prominent feature of many invasive parasitic infections. Gastrointestinal disorders such as chronic hepatitis, ulcerative colitis, Crohn disease, and milk precipitin disease may be associated with eosinophilia. Increased blood eosinophil counts have been identified in several families without association with any specific illness. Rare causes of eosinophilia include the hypereosinophilic syndrome, characterized by counts greater than 1500/μL and organ involvement and damage (hepatosplenomegaly, cardiomyopathy, pulmonary fibrosis, and central nervous system injury). This is a disorder of middle-aged adults and is rare in children. Eosinophilic leukemia has been described, but its existence as a distinct entity is very rare.

Eosinophils are sometimes the last type of mature myeloid cell to disappear after marrow ablative chemotherapy. Increased eosinophil counts are associated with graft-versus-host disease after bone marrow transplant, and elevations are sometimes documented during rejection episodes in patients who have solid organ grafts.

**BLEEDING DISORDERS**

Bleeding disorders may occur as a result of (1) quantitative or qualitative abnormalities of platelets, (2) quantitative or qualitative abnormalities in plasma procoagulant factors, (3) vascular abnormalities, or (4) accelerated fibrinolysis. The coagulation cascade and fibrinolytic system are shown in Figures 30–4 and 30–5.

The most critical aspect in evaluating the bleeding patient is obtaining detailed personal and family bleeding histories, including bleeding complications associated with dental interventions, surgeries, suture placement and removal, and trauma. Excessive mucosal bleeding is suggestive of a platelet disorder, von Willebrand disease (vWD), dysfibrinogenemia, or vasculitis. Bleeding into muscles and joints may be associated with a plasma procoagulant factor abnormality. In either scenario, the abnormality may be congenital or acquired. A thorough physical examination should be performed with special attention to the skin, oro- and nasopharynx, liver, spleen, and joints. Screening and diagnostic evaluation in patients with suspected bleeding disorders should initially include the following laboratory testing:

2. Activated partial thromboplastin time (aPTT) to assess clotting function of high-molecular-weight kininogen, prekallikrein, XII, XI, IX, VIII, X, V, II, and fibrinogen.
3. Platelet count and size determined as part of a CBC.
4. Platelet functional assessment by platelet function analyzer-100 (PFA-100), template bleeding time, or whole blood platelet aggregometry.
5. Fibrinogen functional level by clotting assay.

The following laboratory tests may also be useful:

1. Thrombin time to measure the generation of fibrin from fibrinogen following conversion of prothrombin to thrombin, as well as the antithrombin effects of fibrin-split products and heparin. The thrombin time
Chapter 30

1. Idiopathic Thrombocytopenic Purpura

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Otherwise healthy child.
- Decreased platelet count.
- Petechiae, ecchymoses.

General Considerations

Acute idiopathic thrombocytopenic purpura (ITP) is the most common bleeding disorder of childhood. It occurs most frequently in children aged 2–5 years and often follows infection with viruses, such as rubella, varicella, measles, parvovirus, influenza, EBV, or acute and chronic HIV. Most patients recover spontaneously within a few months. Chronic ITP (> 12 months’ duration) occurs in 10%–20% of affected patients. The thrombocytopenia results from clearance of circulating IgM- or IgG-coated platelets by the reticuloendothelial system. The spleen plays a predominant role in the disease by forming the platelet cross-reactive antibodies and sequestering the antibody-bound platelets.

Clinical Findings

A. Symptoms and Signs

Onset of ITP is usually acute, with the appearance of multiple petechiae and ecchymoses. Epistaxis is also common at presentation. No other physical findings are usually present. Rarely, concurrent infection with EBV or CMV may cause hepatosplenomegaly or lymphadenopathy, simulating acute leukemia.

B. Laboratory Findings

1. Blood—The platelet count is markedly reduced (usually < 50,000/µL and often < 10,000/µL), and platelets frequently are of larger size on peripheral blood smear, suggesting accelerated production of new platelets. The white blood count and differential are normal, and the hemoglobin concentration is preserved unless hemorrhage has been significant.

2. Bone marrow—The number of megakaryocytes is increased. Erythroid and myeloid cellularity is normal.

3. Other laboratory tests—Platelet-associated IgG or IgM, or both, may be demonstrated on the patient’s platelets or in the serum. PT and aPTT are normal.

Abnormalities of Platelet Number or Function

Thrombocytopenia in the pediatric age range is often immune-mediated (eg, ITP, neonatal auto- or alloimmune thrombocytopenia, heparin-induced thrombocytopenia), but is also caused by consumptive coagulopathy (eg, DIC, Kasabach-Merritt syndrome), acute leukemias, rare disorders such as Wiskott-Aldrich syndrome and type 2b vWD, and artifactually in automated cytometers (eg, Bernard-Soulier syndrome), where giant forms may not be enumerated as platelets by automated cell counters.

Figure 30–5. The fibrinolytic system. Solid arrows indicate activation; dashed line arrows indicate inhibition. ECM, extracellular matrix; FDP, fibrinogen-fibrin degradation products; MMP, matrix metalloproteinases; PAI, plasminogen activator inhibitor; TAFI, thrombin activatable fibrinogenolysis inhibitor; tPA, tissue plasminogen activator; uPA, urokinase; uPAR, cellular urokinase receptor. may be prolonged in the setting of a normal fibrinogen concentration if the fibrinogen is dysfunctional (ie, dysfibrinogenemia).

2. Euglobulin lysis time (ELT), if available, to evaluate for accelerated fibrinolysis if the preceding workup is nonrevealing despite documented history of pathologic bleeding. If the ELT is shortened, assessment of plasminogen activator inhibitor-1 and α2-antiplasmin is warranted, as congenital deficiency in these fibrinolytic inhibitors may cause hyperfibrinolysis. In ill patients, measurement of fibrin degradation products may assist in the diagnosis of DIC.
**Differential Diagnosis**

Table 30–7 lists common causes of thrombocytopenia. ITP is a diagnosis of exclusion. Family history or the finding of predominantly giant platelets on the peripheral blood smear is helpful in separating from thrombocytopenia that is hereditary. Bone marrow examination should be performed if the history is atypical (ie, the child is not otherwise healthy, or if there is a family history of bleeding), if abnormalities other than purpura and petechiae are present on physical examination, or if other cell lines are affected on the CBC. The importance of performing a bone marrow examination prior to using corticosteroids in the treatment for ITP remains controversial.

**Complications**

Severe hemorrhage and bleeding into vital organs are the feared complications of ITP. Intracranial hemorrhage is the most serious (but rarely seen) complication, occurring in less than 1% of affected children. The most important risk factors for hemorrhage are a platelet count less than 10,000/μL and mean platelet volume less than 8 fL.

**Treatment**

**A. General Measures**

Treatment is optional in most children in the absence of bleeding. Aspirin and other medications (eg, NSAIDs such as Advil, Naproxin, etc) that compromise platelet function should be avoided. Bleeding precautions (eg, restriction from physical contact activities and use of helmets) should be observed. Platelet transfusion should be avoided except in circumstances of life-threatening bleeding, in which case emergent splenectomy may be considered. In this setting, administration of corticosteroids and IVIG is also advisable.

**B. Corticosteroids**

Patients with clinically significant but non–life-threatening bleeding (ie, epistaxis, hematuria, and hematochezia) and those with a platelet count of less than 10,000/μL may benefit from prednisone at 1–2 mg/kg/d for 2–3 weeks with a maximum dose of 60–80 mg/d. A higher dose initially (3–5 mg/kg/d) for 3–7 days may lead to faster count recovery. The dosage is then tapered and stopped. No further prednisone is given regardless of the platelet count unless significant bleeding recurs, at which time prednisone is administered in the smallest dose that achieves resolution of bleeding episodes (usually 2.5–5 mg twice daily). Follow-up continues until the steroid can again be discontinued, spontaneous remission occurs, or other therapeutic measures are instituted. Toxicity (Cushingoid facies, weight gain, change in behavior, hyperglycemia, and hypertension) is usually mild for short treatment courses.

**C. Intravenous Immunoglobulin**

Intravenous immunoglobulin (IVIG) is the treatment of choice for severe, acute bleeding, and may also be used as an alternative or adjunct to corticosteroid treatment in both acute and chronic ITP of childhood. IVIG may be effective even when the patient is resistant to corticosteroids; responses are prompt and may last for several weeks. Most patients receive 0.8–1 g/kg/d for 1–2 days. Infusion time is typically 4–6 hours. Platelets may be given simultaneously during life-threatening hemorrhage but are rapidly destroyed. Adverse effects of IVIG are common, including transient neurologic complications in one-third of patients (eg, headache, nausea, and aseptic meningitis). These symptoms may mimic those of intracranial hemorrhage and necessitate radiologic evaluation of the brain. A transient decrease in neutrophil number may also be seen.

D. Anti-Rh(D) Immunoglobulin

This polyclonal immunoglobulin binds to the D antigen on RBCs. The splenic clearance of anti-D–coated red cells interferes with removal of antibody-coated platelets, resulting in improvement in thrombocytopenia. This approach is effective only in Rh(+) patients with a functional spleen. The time required for platelet increase is slightly longer than with IVIG. However, approximately 80% of Rh(+) children with acute or chronic ITP respond well. Significant hemolysis may occur transiently with an average hemoglobin concentration decrease of 0.8 g/dL. However, severe hemolysis occurs in 5% of treated children, and clinical and laboratory evaluation following administration is warranted in all patients. Rh(D) immunoglobulin is less expensive and infused more rapidly than IVIG but is more expensive than corticosteroids.

E. Splenectomy

Many children with chronic ITP have platelet counts greater than 30,000/μL. Up to 70% of such children spontaneously recover with a platelet count greater than 100,000/μL within 1 year. For the remainder, corticosteroids, IVIG, and anti-D immunoglobulin are typically effective treatment for acute bleeding. Splenectomy produces a response in 70%–80%, but it should be considered only after persistence of significant thrombocytopenia for at least 1 year. Preoperative treatment with corticosteroids, IVIG, or anti-D immunoglobulin is usually indicated. Postoperatively, the platelet count may rise to 1 million/μL. This reactive thrombocytosis is not associated with thrombotic complications in children. The risk of overwhelming infection (predominantly with encapsulated organisms) is increased after splenectomy, particularly in the young child. Therefore, the procedure should be postponed, if possible, until age 5 years. Administration of pneumococcal, *H. influenzae* type b and meningococcal vaccines at least 2 weeks prior to splenectomy is recommended. Daily penicillin prophylaxis should be started postoperatively and continued at least until 5 years of age.

F. Rituximab (Anti-CD20 Monoclonal Antibody)

There have been no randomized trials for rituximab in children. The efficacy of treating childhood chronic ITP in several series and case studies has demonstrated a response rate of 60%. Because of significant adverse events, this therapy may be reserved for refractory cases with significant bleeding or as an alternative to splenectomy.

G. New Agents

One randomized clinical trial in children has been conducted with romiplostim, a thrombopoietin receptor agonist, with an 88% response rate and improved quality of life. Further studies in larger numbers of pediatric patients are needed to address the possibility that some patients with chronic ITP have a response in platelet production that is not maximally increased.

### Prognosis

Ninety percent of children with ITP will have a spontaneous remission. Features associated with the development of chronic ITP include female gender, age greater than 10 years at presentation, insidious onset of bruising, and the presence of other autoantibodies. Older child- and adolescent-onset ITP is associated with an increased risk of chronic autoimmune diseases or immunodeficiency states. Appropriate screening by history and laboratory studies (eg, antinuclear antibody) is warranted.

---

2. Thrombocytopenia in the Newborn

Thrombocytopenia is one of the most common causes of neonatal hemorrhage and should be considered in any newborn with petechiae, purpura, or other significant bleeding. Defined as a platelet count less than 150,000/μL, thrombocytopenia occurs in approximately 0.9% of unselected neonates. Several specific entities may be responsible (see Table 30–7); however, half of such neonates have alloimmune thrombocytopenia. Infection and DIC are the most common causes of thrombocytopenia in ill full-term newborns and in preterm newborns. In the healthy neonate, antibody-mediated thrombocytopenia (alloimmune or maternal autoimmune), viral syndromes, hyperviscosity, and major-vessel thrombosis are frequent causes of thrombocytopenia. Management is directed toward the underlying etiology.

A. Thrombocytopenia Associated With Platelet Alloantibodies (Neonatal Alloimmune Thrombocytopenia)

Platelet alloimmunization occurs in 1 out of approximately 350 pregnancies. Unlike in Rh incompatibility, 30%–40% of affected neonates are first-born. Thrombocytopenia is progressive over the course of gestation and worse with each subsequent pregnancy. Alloimmunization occurs when a platelet antigen of the infant differs from that of the mother, and the mother is sensitized by fetal platelets that cross
the placenta into the maternal circulation. In Caucasians, alloimmune thrombocytopenia is most often due to human platelet antigen (HPA)-1a incompatibility. Sensitization of a mother homozygous for HPA-1b to paternally acquired fetal HPA-1a antigen results in severe fetal thrombocytopenia in 1 in 1200 fetuses. Only 1 in 20 HPA-1a–positive fetuses of HPA-1a–negative mothers develop alloimmunization. Other platelet-specific alloantigens may be etiologic. The presence of antenatal maternal platelet antibodies on more than one occasion and their persistence into the third trimester is predictive of severe neonatal thrombocytopenia; a weak or undetectable antibody does not exclude thrombocytopenia. Severe intracranial hemorrhage occurs in 10%–30% of affected neonates as early as 20 weeks’ gestation. Petechiae or other bleeding manifestations are usually present shortly after birth. The disease is self-limited, and the platelet count normalizes within 4 weeks.

If alloimmunization is associated with clinically significant bleeding, transfusion of platelet concentrates harvested from the mother is more effective than random donor platelets in increasing the platelet count. Transfusion with HPA-matched platelets from unrelated donors or treatment with IVIG or methylprednisolone to acutely block macrophage uptake of sensitized cells has also been successful in raising the platelet count and achieving hemostasis. If thrombocytopenia is not severe and bleeding is absent, observation alone is often appropriate.

Intracranial hemorrhage in a previous child secondary to alloimmune thrombocytopenia is the strongest risk factor for severe fetal thrombocytopenia and hemorrhage in a subsequent pregnancy. Amniocentesis or chorionic villus sampling to obtain fetal DNA for platelet antigen typing is sometimes performed if the father is heterozygous for HPA-1a. If alloimmunization has occurred with a previous pregnancy, irrespective of history of intracranial hemorrhage, screening cranial ultrasound for hemorrhage should begin at 20 weeks’ gestation and be repeated regularly. In addition, cordocentesis should be performed at approximately 20 weeks’ gestation, with prophylactic transfusion of irradiated, leukoreduced, maternal platelet concentrates. If the fetal platelet count is less than 100,000/μL, the mother should be treated with weekly IVIG. Delivery by elective cesarean section is recommended if the fetal platelet count is less than 50,000/μL, to minimize the risk of intracranial hemorrhage associated with birth trauma.

B. Thrombocytopenia Associated With ITP in the Mother (Neonatal Autoimmune Thrombocytopenia)

Infants born to mothers with idiopathic thrombocytopenic purpura (ITP) or other autoimmune diseases (eg, antiphospholipid antibody syndrome or systemic lupus erythematosus) may develop thrombocytopenia as a result of transfer of antiplatelet IgG from the mother to the infant. Unfortunately, maternal and fetal platelet counts and maternal antiplatelet antibody levels are unreliable predictors of bleeding risk. Antenatal corticosteroid administration to the mother is generally instituted once maternal platelet count falls below 50,000/μL, with or without a concomitant course of IVIG.

Most neonates with autoimmune thrombocytopenia do not develop clinically significant bleeding, and thus treatment for thrombocytopenia is not often required. The risk of intracranial hemorrhage is 0.2%–2%. If diffuse petechiae or minor bleeding are evident, a 1- to 2-week course of oral prednisone, 2 mg/kg/d, may be helpful. If the platelet count remains consistently less than 20,000/μL or if severe hemorrhage develops, IVIG should be given (0.8–1 g/kg daily for 1–2 days). Platelet transfusions are only indicated for life-threatening bleeding, and may only be effective after removal of antibody by exchange transfusion. The platelet nadir is typically between the fourth and sixth day of life and improves significantly by 1 month; full recovery may take 2–4 months. Platelet recovery may be delayed in breast-fed infants because of transfer of IgG to the milk.

C. Neonatal Thrombocytopenia Associated With Infections

Thrombocytopenia is commonly associated with severe generalized infections during the newborn period. Between 50% and 75% of neonates with bacterial sepsis are thrombocytopenic. Intrauterine infections such as rubella, syphilis, toxoplasmosis, CMV, herpes simplex (acquired intra- or postpartum), enteroviruses, and parvovirus are often associated with thrombocytopenia. In addition to specific treatment for the underlying disease, platelet transfusions may be indicated in severe cases.

D. Thrombocytopenia Associated With Kaposiform Hemangioendotheliomas (Kasabach-Merritt Syndrome)

A rare but important cause of thrombocytopenia in the newborn is kaposiform hemangioendotheliomas, a benign neoplasm with histopathology distinct from that of classic infantile hemangiomas. Intense platelet sequestration in the lesion results in peripheral thrombocytopenia and may rarely be associated with a DIC-like picture and hemolytic anemia. The bone marrow typically shows megakaryocytic hyperplasia in response to the thrombocytopenia. Corticosteroids, α-interferon, and vincristine are all useful for reducing the size of the lesion and are indicated if significant coagulopathy is present, the lesion compresses a vital structure, or the lesion is cosmetically unacceptable. If consumptive coagulopathy is present, heparin or aminocaproic acid may be useful. Depending on the site, embolization may be an option. Surgery is often avoided because of the high risk of hemorrhage.
3. Disorders of Platelet Function

Individuals with platelet function defects typically develop abnormal bruising and mucosal bleeding similar to that occurring in persons with thrombocytopenia. Historically, platelet function has been screened by measuring the bleeding time. If this is prolonged, in vitro platelet aggregation is studied using agonists, such as adenosine diphosphate, collagen, arachidonic acid, and ristocetin. While labor-intensive, platelet aggregometry remains important in selected clinical situations, the PFA-100 has become available to evaluate platelet dysfunction and vWD and has replaced the template bleeding time in many clinical laboratories. Unfortunately, none of these screening tests of platelet function is uniformly predictive of clinical bleeding severity.

Platelet dysfunction may be inherited or acquired, with the latter being more common. Acquired disorders of platelet function may occur secondary to uremia, cirrhosis, sepsis, myeloproliferative disorders, congenital heart disease, and viral infections. Many pharmacologic agents decrease platelet function. The most common offending agents in the pediatric population are aspirin and other NSAIDs, synthetic penicillins, and valproic acid. In acquired platelet dysfunction, the PFA-100 closure time is typically prolonged with collagen-eptinephrine, while normal with collagen-ADP.

The inherited disorders are due to defects in platelet-vessel interaction, platelet-platelet interaction, platelet granule content or release (including defects of signal transduction), thromboxane and arachidonic acid pathway, and platelet-procoagulant protein interaction. Individuals with hereditary platelet dysfunction generally have a prolonged bleeding time with normal platelet number and morphology by light microscopy. PFA-100 closure time, in contrast to that in acquired dysfunction, is typically prolonged with both collagen-ADP and collagen-eptinephrine.

Congenital causes of defective platelet-vessel wall interaction include Bernard-Soulier syndrome, which is characterized by increased platelet size and decreased platelet number. The molecular defect in this autosomal recessive disorder is a deficiency or dysfunction of glycoprotein Ib-V-IX complex on the platelet surface resulting in impaired von Willebrand factor (vWF) binding, and hence, impaired platelet adhesion to the vascular endothelium.

Glanzmann thrombasthenia is an example of platelet-platelet dysfunction. In this autosomal recessive disorder, glycoprotein IIb-IIIa is deficient or dysfunctional. Platelets do not bind fibrinogen effectively and exhibit impaired aggregation. As in Bernard-Soulier syndrome, acute bleeding is treated by platelet transfusion.

Disorders involving platelet granule content include storage pool disease and Quebec platelet disorder. In individuals with storage pool disease, platelet-dense granules lack adenosine diphosphate and adenosine triphosphate and are often found to be low in number by electron microscopy. These granules are also deficient in Hermansky-Pudlak, Chédiak-Higashi, and Wiskott-Aldrich syndromes. Whereas deficiency of a second granule class, α-granules, results in the gray platelet syndrome, Quebec platelet disorder is characterized by a normal platelet α-granule number, but with abnormal proteolysis of α-granule proteins and deficiency of platelet α-granule multimerin. α-Granule abnormality in this disorder also results in increased serum levels of urokinase-type plasminogen activator. Epinephrine-induced platelet aggregation is markedly impaired.

Platelet dysfunction has also been observed in other congenital syndromes, such as Down and Noonan syndromes, without a clear understanding of the molecular defect.

**Treatment**

Acute bleeding in many individuals with acquired or selected congenital platelet function defects responds to therapy with desmopressin acetate, likely due to an induced release of vWF from endothelial stores and/or upregulated expression of glycoprotein Ib-V-IX on the platelet surface. If this therapy is ineffective, or if the patient has Bernard-Soulier syndrome or Glanzmann syndrome, the mainstay of treatment for bleeding episodes is platelet transfusion, possibly with HLA type-specific platelets. Recombinant VWF has variable efficacy and may be helpful in platelet transfusion-refractory patients.

**INHERITED BLEEDING DISORDERS**

Table 30–8 lists normal values for coagulation factors. The more common factor deficiencies are discussed in this section. Individuals with bleeding disorders should avoid exposure to medications that inhibit platelet function. Participation in contact sports should be considered in the context of the severity of the bleeding disorder.

**1. Factor VIII Deficiency (Hemophilia A, Classic Hemophilia)**

- **Bruising, soft-tissue bleeding, hemarthrosis.**
- **Prolonged aPTT.**
- **Reduced factor VIII activity.**

Except as otherwise indicated values are mean ±2 standard deviation (SD) or values in parentheses are lower limits (−2 SD or lower range); +, positive or present; ↓, decreased; ↑, increased; N, normal or no change; *, values as ratio or subject/mean of reference range; α₂-MG, α₂-macroglobulin; α₂-AP, α₂-antiplasmin; ADP, adenosine diphosphate; AT, antithrombin; BT, bleeding time; C1IN, C1 esterase inhibitor; HK, high-molecular-weight kininogen; PAI, plasminogen activator inhibitor; PC, protein C; PreK, prekallikrein; PS, protein S; PT, prothrombin time; PTT, partial thromboplastin time; TCT, thrombin clotting time; TFPI, tissue factor pathway inhibitor; tPA, tissue plasminogen activator; vWF, von Willebrand factor. Overall fibrinolysis is measured by euglobulin lysis time.

General Considerations

Factor VIII activity is reported in units per milliliter, with 1 U/mL equal to 100% of the factor activity found in 1 mL of normal plasma. The normal range for factor VIII activity is 0.50–1.50 U/mL (50%–150%). Hemophilia A occurs predominantly in males as an X-linked disorder. One-third of cases are due to a new mutation. The incidence of factor VIII deficiency is 1:5000 male births.

Clinical Findings

A. Symptoms and Signs

Patients with severe hemophilia A (<1% plasma factor VIII activity) have frequent spontaneous bleeding episodes involving skin, mucous membranes, joints, muscles, and viscera. In contrast, patients with mild hemophilia A (5%–40% factor VIII activity) bleed only at times of trauma or surgery. Those with moderate hemophilia A (1% to <5% factor VIII activity) typically have intermediate bleeding manifestations. The most crippling aspect of factor VIII deficiency is the tendency to develop recurrent hemorrhages that incite joint destruction.

B. Laboratory Findings

Individuals with hemophilia A have a prolonged aPTT, except in some cases of mild deficiency. The PT is normal. The diagnosis is confirmed by finding decreased factor VIII activity with normal vWF activity. In two-thirds of families of hemophilic patients, the females are carriers and some are mildly symptomatic. Carriers of hemophilia can be suspected by determination of the ratio of factor VIII activity to vWF antigen and definitely diagnosed by molecular genetic techniques. In a male fetus or newborn with a family history of hemophilia A, cord blood sampling for factor VIII activity is accurate and important in subsequent care.

Complications

Intracranial hemorrhage is the leading disease-related cause of death among patients with hemophilia. Most intracranial hemorrhages in moderate to severe deficiency are spontaneous (ie, not associated with trauma). Hemarthroses begin early in childhood and, particularly when recurrent, can result in joint destruction (ie, hemophilic arthropathy). Large intramuscular hematomas can lead to a compartment syndrome with resultant neurologic compromise. Although these complications are most common in severe hemophilia A, they may be experienced by individuals with moderate or mild disease. A serious complication of hemophilia is the development of an acquired circulating antibody to factor VIII after treatment with factor VIII concentrate. Such factor VIII inhibitors develop in up to 30% of patients with severe hemophilia A, and most commonly among patients with large deletions in the factor VIII gene. Inhibitors may be amenable to desensitization with regular factor VIII infusion (immune tolerance therapy) with or without immunosuppressive therapy. The “bypassing agent,” recombinant factor VIIa, has become a therapy of choice for treatment of acute hemorrhage in patients with hemophilia A and a high-titer inhibitor.

In prior decades, therapy-related complications in hemophilia A have included infection with the HIV, hepatitis B virus, and hepatitis C virus. Through stringent donor selection, the implementation of sensitive screening assays, the use of heat or chemical methods for viral inactivation, and the development of recombinant products, the risk of these infections is minimal. Inactivation methods do not eradicate viruses lacking a lipid envelope, however, so that transmission of parvovirus and hepatitis A remains a concern with the use of plasma-derived products. Immunization with hepatitis A and hepatitis B vaccines is recommended for all hemophilia patients.

Treatment

The general aim of management is to raise the factor VIII activity to prevent or stop bleeding. Some patients with mild factor VIII deficiency may respond to desmopressin via release of endothelial stores of factor VIII and vWF into plasma; however, most patients require administration of exogenous factor VIII to achieve hemostasis. The in vivo half-life of factor VIII is generally 8–12 hours but may exhibit considerable variation among individuals depending on comorbid conditions. Non–life-threatening, non–limb-threatening hemorrhage is treated initially with 20–30 U/kg of factor VIII, to achieve a rise in plasma factor VIII activity to 40%–60%. Large joint hemarthrosis and life- or limb-threatening hemorrhage is treated initially with approximately 50 U/kg of factor VIII, targeting a rise to 100% factor VIII activity. Subsequent doses are determined according to the site and extent of bleeding and the clinical response. In circumstances of suboptimal clinical response, recent change in bleeding frequency, or comorbid illness, monitoring the plasma factor VIII activity response may be warranted. For most instances of non–life-threatening hemorrhage in experienced patients with moderate or severe hemophilia A, treatment can be administered at home, provided adequate intravenous access and close contact with the hemophilia clinician team can be achieved.

Prophylactic factor VIII infusions (eg, two or three times weekly) may prevent the development of arthropathy in severe hemophiliacs, and this approach is the standard of care in pediatric hemophilia.

Prognosis

The development of safe and effective therapies for hemophilia A has resulted in improved long-term survival in recent decades. In addition, more aggressive management and the coordination of comprehensive care through hemophilia centers have greatly improved quality of life and level of function.
2. Factor IX Deficiency (Hemophilia B, Christmas Disease)

The mode of inheritance and clinical manifestations of factor IX deficiency are the same as those of factor VIII deficiency. Hemophilia B is 15%–20% as prevalent as hemophilia A. As in factor VIII deficiency, factor IX deficiency is associated with a prolonged aPTT, but the PT and thrombin time are normal. However, the aPTT is slightly less sensitive to factor IX deficiency than factor VIII deficiency. Diagnosis of hemophilia B is made by assaying factor IX activity, and severity is determined similarly to factor VIII deficiency. In general, clinical bleeding severity correlates less well with factor activity in hemophilia B than in hemophilia A.

The mainstay of treatment in hemophilia B is exogenous factor IX. Unlike factor VIII, about 50% of the administered dose of factor IX diffuses into the extravascular space. Therefore, 1 U/kg of plasma-derived factor IX concentrate or recombinant factor IX is expected to increase plasma factor IX activity by approximately 1%. Factor IX typically has a half-life of 20–22 hours in vivo, but because of variability, therapeutic monitoring may be warranted. As for factor VIII products, viral-inactivation techniques for plasma-derived factor IX concentrates appear effective in eradicating enveloped viruses. Only 1%–3% of persons with factor IX deficiency develop an inhibitor to factor IX, but patients may be at risk for anaphylaxis when receiving exogenous factor IX. The prognosis for persons with factor IX deficiency is comparable to that of patients with factor VIII deficiency. Gene therapy research efforts are ongoing for both hemophilias.

4. Other Inherited Bleeding Disorders

Other hereditary single clotting factor deficiencies are rare. Transmission is generally autosomal. Homozygous individuals with a deficiency or structural abnormality of prothrombin, factor V, factor VII, or factor X may have excessive bleeding.

Persons with dysfibrinogenemia (ie, structurally or functionally abnormal fibrinogen) may develop recurrent venous thromboembolic episodes or bleeding. Immunologic assay of fibrinogen is normal, but clotting assay may be low and the thrombin time prolonged. The PT and aPTT may be prolonged. Cryoprecipitate, which is rich in fibrinogen, has been the treatment of choice. Fibrinogen concentrates are available in the United States, but the clinical experience is limited.

Afibrinogenemia resembles hemophilia clinically but has an autosomal recessive inheritance. Affected patients can experience a variety of bleeding manifestations, including mucosal bleeding, ecchymoses, hematomas, hemarthroses, and intracranial hemorrhage, especially following trauma. Fatal umbilical cord hemorrhage has been reported in neonates. The PT, aPTT, and thrombin time are all prolonged. A severely reduced fibrinogen concentration in an otherwise well child is confirmatory of the diagnosis. As in dysfibrinogenemia, fibrinogen concentrate or cryoprecipitate infusion is used for surgical prophylaxis and for acute hemorrhage.

Prolonged PFA-100 (or bleeding time), normal platelet count, absence of acquired platelet dysfunction.

Reduced activity or abnormal structure of vWF.

General Considerations

von Willebrand disease (vWD) is the most common inherited bleeding disorder among Caucasians, with a prevalence of 1%. vWF is a protein present as a multimeric complex in plasma, which binds factor VIII and is a cofactor for platelet adhesion to the endothelium. An estimated 70%-80% of all patients with vWD have classic vWD (type 1), which is caused by a partial quantitative deficiency of vWF. vWD type 2 involves a qualitative deficiency of (ie, dysfunctional) vWF, and vWD type 3 is characterized by a nearly complete deficiency of vWF. The majority (> 80%) of individuals with type 1 disease are asymptomatic. vWD is most often transmitted as an autosomal dominant trait, but it can be autosomal recessive. The disease can also be acquired, developing in association with hypothyroidism, Wilms tumor, cardiac disease, renal disease, or systemic lupus erythematosus, and in individuals receiving valproic acid. Acquired vWD is most often caused by the development of an antibody to vWF or increased turnover of vWF.

Clinical Findings

A. Symptoms and Signs
A history of increased bruising and excessive epistaxis is often present. Prolonged bleeding also occurs with trauma or at surgery. Menorrhagia is often a presenting finding in females.

B. Laboratory Findings
PT is normal, and aPTT is sometimes prolonged. Prolongation of the PFA-100 or bleeding time is usually present since vWF plays a role in platelet adherence to endothelium. Platelet number may be decreased in type 2b vWD. Factor VIII and vWF antigen are decreased in types 1 and 3, but may be normal in type 2 vWD. vWF activity (eg, ristocetin cofactor or collagen binding) is decreased in all types. Since normal vWF antigen levels vary by blood type (type O normally has lower levels), blood type must be determined. Complete laboratory classification requires vWF multimer assay. The diagnosis requires confirmation of laboratory testing and bleeding history is often helpful when present.

Treatment

The treatment to prevent or halt bleeding for most patients with vWD types 1 and 2 is desmopressin acetate, which causes release of vWF from endothelial stores. Desmopressin may be administered intravenously at a dose of 0.3 mcg/kg diluted in at least 20–30 mL of normal saline and given over 20–30 minutes. This dose typically elicits a three- to fivefold increase in plasma vWF. A high-concentration desmopressin nasal spray (150 mcg/spray), different than the preparation used for enuresis, may alternatively be used. Because response to vWF is variable among patients, factor VIII and vWF activities are typically measured before 60 minutes and 4 hours after infusion, to document the adequacy of the response. Desmopressin may cause fluid shifts, hyponatremia, and seizures; therefore, fluid restriction should be discussed, especially in children younger than 2 years. Because release of stored vWF is limited, tachyphylaxis often occurs with desmopressin.

If further therapy is indicated, vWF-replacement therapy (eg, plasma-derived concentrate) is recommended; such therapy is also used in patients with type 1 or 2a vWD who exhibit suboptimal laboratory response to desmopressin, and for all individuals with type 2b or 3 vWD. Antifibrinolytic agents (eg, e-aminocaproic acid) may be useful for control of mucosal bleeding. Topical thrombin and fibrin glue may also be of benefit, although antibodies that inhibit these clotting proteins and therefore the affect of the glue have been described. Estrogen-containing contraceptive therapy may be helpful for menorrhagia.

Prognosis

With the availability of effective treatment and prophylaxis for bleeding, life expectancy in vWD is normal.

ACQUIRED BLEEDING DISORDERS

1. Disseminated Intravascular Coagulation

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Presence of disorder known to trigger DIC.

Evidence for consumptive coagulopathy (prolonged aPTT, PT, or bleeding time; increase in FSPs [fibrin-fibrinogen split products]; decreased fibrinogen or platelets).

General Considerations

Disseminated intravascular coagulation (DIC) is an acquired pathologic process characterized by tissue factor–mediated coagulation activation in the host. DIC involves dysregulated,
excessive thrombin generation, with consequent intravascular fibrin deposition and consumption of platelets and procoagulant factors. Microthrombi, composed of fibrin and platelets, may produce tissue ischemia and end-organ damage. The fibrinolytic system is frequently activated in DIC, leading to plasmin-mediated destruction of fibrin and fibrinogen; this results in fibrin-fibrinogen degradation products (FDPs) which exhibit anticoagulant and platelet-inhibitory functions. DIC commonly accompanies severe infection and other critical illnesses in infants and children. Conditions known to trigger DIC include endothelial damage (eg, endotoxin, virus), tissue necrosis (eg, burns), diffuse ischemic injury (eg, shock, hypoxia acidosis), and systemic release of tissue procoagulants (eg, certain cancers, placental disorders).

**Clinical Findings**

**A. Symptoms and Signs**

Signs of DIC may include (1) signs of shock, often including end-organ dysfunction, (2) diffuse bleeding tendency (eg, hematuria, melena, purpura, petechiae, persistent oozing from needle punctures or other invasive procedures), and (3) evidence of thrombotic lesions (eg, major vessel thrombosis, purpura fulminans).

**B. Laboratory Findings**

Tests that are most sensitive, easiest to perform, most useful for monitoring, and best reflect the hemostatic capacity of the patient are the PT, aPTT, platelet count, fibrinogen, and FSPs. The PT and aPTT are typically prolonged and the platelet count and fibrinogen concentration may be decreased. However, in children, the fibrinogen level may be normal until late in the course. Levels of FSPs are increased, and elevated levels of D-dimer, a cross-linked fibrin degradation byproduct, may be helpful in monitoring the degree of activation of both coagulation and fibrinolysis. However, D-dimer is nonspecific and may be elevated in the context of a triggering event (eg, severe infection) without concomitant DIC. Often, physiologic inhibitors of coagulation, especially antithrombin III and protein C, are consumed, predisposing to thrombosis. The specific laboratory abnormalities in DIC may vary with the triggering event and the course of illness.

**Differential Diagnosis**

DIC can be difficult to distinguish from coagulopathy of liver disease (ie, hepatic synthetic dysfunction), especially when the latter is associated with thrombocytopenia secondary to portal hypertension and hypersplenism. Generally, factor VII activity is decreased markedly in liver disease (due to deficient synthesis of this protein, which has the shortest half-life among the procoagulant factors), but only mildly to moderately decreased in DIC (due to consumption). Factor VIII activity is often normal or even increased in liver disease, but decreased in DIC.

**Treatment**

**A. Therapy for Underlying Disorder**

The most important aspect of therapy in DIC is the identification and treatment of the triggering event. If the pathogenic process underlying DIC is reversed, often no other therapy is needed for the coagulopathy.

**B. Replacement Therapy for Consumptive Coagulopathy**

Replacement of consumed procoagulant factors with FFP and of platelets via platelet transfusion is warranted in the setting of DIC with hemorrhagic complications, or as periprocedural bleeding prophylaxis. Infusion of 10–15 mL/kg FFP typically raises procoagulant factor activities by approximately 10%–15%. Cryoprecipitate can also be given as a rich source of fibrinogen; one bag of cryoprecipitate per 3 kg in infants or one bag of cryoprecipitate per 6 kg in older children typically raises plasma fibrinogen concentration by 75–100 mg/dL.

**C. Anticoagulant Therapy for Coagulation Activation**

Continuous intravenous infusion of unfractionated heparin is sometimes given in order to attenuate coagulation activation and consequent consumptive coagulopathy. The rationale for heparin therapy is to maximize the efficacy of, and minimize the need for, replacement of procoagulants and platelets; however, clinical evidence demonstrating benefit of heparin in DIC is lacking. Prophylactic doses of unfractionated heparin or low-molecular-weight heparin (LMWH) in critically ill and nonbleeding patients with DIC may be considered for prevention of venous thromboembolism. Unfractionated heparin dosing and monitoring is listed on page 979.

**D. Specific Factor Concentrates**

A nonrandomized pilot study of antithrombin concentrate in children with DIC and associated acquired antithrombin deficiency demonstrated favorable outcomes, suggesting that replacement of this consumed procoagulant may be of benefit. Protein C concentrate has also shown promise in two small pilot studies of meningococci-associated DIC with purpura fulminans. Activated protein C has reduced mortality in septic adults in a large randomized multicenter trial; in additional studies, efficacy in adults and pediatrics is increasingly controversial.

**2. Liver Disease**

The liver is the major synthetic site of prothrombin, fibrinogen, high-molecular-weight kininogen, and factors V, VII,
IX, X, XI, XII, and XIII. In addition, plasminogen and the physiologic anticoagulants (antithrombin III, protein C, and protein S) are hepatically synthesized. α₁-Antiplasmin, a regulator of fibrinolysis, is also produced in the liver. Deficiency of factor V and the vitamin K–dependent factors (II, VII, IX, and X) is most often a result of decreased hepatic synthesis and is manifested by a prolonged PT and often a prolonged aPTT. Extravascular loss and increased consumption of clotting factors may contribute to PT and aPTT prolongation. Fibrinogen production is often decreased, or an abnormal fibrinogen (dysfibrinogen) containing excess sialic acid residues may be synthesized, or both. Hypofibrinogenemia or dysfibrinogenemia is associated with prolongation of thrombin time and reptilase time. FDPs and D-dimers may be present because of increased fibrinolysis, particularly in the setting of chronic hepatitis or cirrhosis. Thrombocytopenia secondary to hypersplenism may occur. DIC and coagulopathy of liver disease also mimic vitamin K deficiency; however, vitamin K deficiency has normal factor V activity. Treatment of acute bleeding in the setting of coagulopathy of liver disease consists of replacement with FFP and platelets. Desmopressin may shorten the bleeding time and aPTT in patients with chronic liver disease, but its safety has not been well established. Recombinant VIIa also is efficacious for life-threatening hemorrhage.

3. Vitamin K Deficiency

The newborn period is characterized by physiologically depressed activity of the vitamin K–dependent factors (II, VII, IX, and X). If vitamin K is not administered at birth, a bleeding diathesis previously called hemorrhagic disease of the newborn, now termed vitamin K deficiency bleeding (VKDB), may develop. Outside of the newborn period, vitamin K deficiency may occur as a consequence of inadequate intake, excess loss, inadequate formation of active metabolites, or competitive antagonism.

One of three patterns is seen in the neonatal period:

1. Early VKDB of the newborn occurs within 24 hours of birth and is most often manifested by cephalohematoma, intracranial hemorrhage, or intra-abdominal bleeding. Although occasionally idiopathic, it is most often associated with maternal ingestion of drugs that interfere with vitamin K metabolism (eg, warfarin, phenytoin, isoniazid, and rifampin). Early VKDB occurs in 6%–12% of neonates born to mothers who take these medications without receiving vitamin K supplementation. The disorder is often life threatening.

2. Classic VKDB occurs at 24 hours to 7 days of age and usually is manifested as gastrointestinal, skin, or mucosal bleeding. Bleeding after circumcision may occur. Although occasionally associated with maternal drug usage, it most often occurs in well infants who do not receive vitamin K at birth and are solely breast fed.

3. Late neonatal VKDB occurs on or after day 8. Manifestations include intracranial, gastrointestinal, or skin bleeding. This disorder is often associated with fat malabsorption (eg, in chronic diarrhea) or alterations in intestinal flora (eg, with prolonged antibiotic therapy). Like classic VKDB, late VKDB occurs almost exclusively in breast-fed infants.

The diagnosis of vitamin K deficiency is suspected based on the history, physical examination, and laboratory results. The PT is prolonged out of proportion to the aPTT (also prolonged). The thrombin time becomes prolonged late in the course. The platelet count is normal. This laboratory profile is similar to the coagulopathy of acute liver disease, but with normal fibrinogen level and absence of hepatic transaminase elevation. The diagnosis of vitamin K deficiency is confirmed by a demonstration of noncarboxylated proteins in the absence of vitamin K in the plasma and by clinical and laboratory responses to vitamin K. Intravenous or subcutaneous treatment with vitamin K should be given immediately and not withheld while awaiting test results. In the setting of severe bleeding, additional acute treatment with FFP or recombinant factor VIIa may be indicated.

4. Uremia

Uremia is frequently associated with acquired platelet dysfunction. Bleeding occurs in approximately 50% of patients with chronic renal failure. The bleeding risk conferred by platelet dysfunction associated with metabolic imbalance may be compounded by decreased vWF activity and procoagulant deficiencies (eg, factor II, XII, XI, IX) due to increased urinary losses of these proteins in some settings of renal insufficiency. In accordance with platelet dysfunction, uremic bleeding is typically characterized by purpura, epistaxis, menorrhagia, or gastrointestinal hemorrhage. Acute bleeding may be managed with infusion of desmopressin acetate, factor VIII concentrates containing vWF, or cryoprecipitate with or without coadministration of FFP. Red cell transfusion may be required. Prophylactic administration of erythropoietin before the development of severe anemia appears to decrease the potential for bleeding. Recombinant VIIa may be useful in refractory bleeding.

1. Henoch-Schönlein Purpura (Anaphylactoid Purpura)

**Essentials of Diagnosis & Typical Features**
- Purpuric cutaneous rash.
- Migratory polyarthritis or polyarthralgias.
- Intermittent abdominal pain.
- Nephritis.

**General Considerations**
Henoch-Schönlein purpura (HSP), the most common type of small vessel vasculitis in children, primarily affects boys 2–7 years of age. Occurrence is highest in the spring and fall, and upper respiratory infection precedes the diagnosis in two-thirds of children.

Leukocytoclastic vasculitis in HSP principally involves the small vessels of the skin, gastrointestinal tract, and kidneys, with deposition of IgA immune complexes. The most common and earliest symptom is palpable purpura, which results from extravasation of erythrocytes into the tissue surrounding the involved venules. Antigens from group A β-hemolytic streptococci and other bacteria, viruses, drugs, foods, and insect bites have been proposed as inciting agents.

**Clinical Findings**

**A. Symptoms and Signs**
Skin involvement may be urticarial initially, progresses to a maculopapules, and coalesces to a symmetrical, palpable purpuric rash distributed on the legs, buttocks, and elbows. New lesions may continue to appear for 2–4 weeks, and may extend to involve the entire body. Two-thirds of patients develop migratory polyarthalgias or polyarthritis, primarily of the ankles and knees. Intermittent, sharp abdominal pain occurs in approximately 50% of patients, and hemorrhage and edema of the small intestine can often be demonstrated. Intussusception may develop. From 25% to 50% of those affected develop renal involvement in the second or third week of illness with either a nephritic or, less commonly, nephrotic picture. Hypertension may accompany the renal involvement. In males, testicular torsion may also occur, and neurologic symptoms are possible due to small vessel vasculitis.

**B. Laboratory Findings**
The platelet count is normal or elevated, and other screening tests of hemostasis and platelet function are typically normal. Urinalysis frequently reveals hematuria, and sometimes proteinuria. Stool may be positive for occult blood. The antistreptolysin O (ASO) titer is often elevated and the throat culture positive for group A β-hemolytic streptococci. Serum IgA may be elevated.

**Differential Diagnosis**
The rash of septicemia (especially meningococcemia) may be similar to skin involvement in HSP, although the distribution tends to be more generalized. The possibility of trauma should be considered in any child presenting with purpura. Other vasculitides should also be considered. The lesions of thrombotic thrombocytopenic purpura (TTP) are not palpable.

**Treatment**
Generally, treatment is supportive. NSAIDs may be useful for the arthritis. Corticosteroid therapy may provide symptomatic relief for severe gastrointestinal or joint manifestations but does not alter skin or renal manifestations. If culture for group A β-hemolytic streptococci is positive or if the ASO titer is elevated, a therapeutic course of penicillin is warranted.

**Prognosis**
The prognosis for recovery is generally good, although symptoms frequently (25%–50%) recur over a period of several months. In patients who develop renal manifestations, microscopic hematuria may persist for years. Progressive renal failure occurs in fewer than 5% of patients with HSP, with an overall fatality rate of 3%.

2. Collagen Disorders
Mild to life-threatening bleeding occurs with some types of Ehlers-Danlos syndrome, the most common inherited collagen disorder. Ehlers-Danlos syndrome is characterized by joint hypermobility, skin extensibility, and easy bruising. Coagulation abnormalities may sometimes be present, including platelet dysfunction and deficiencies of coagulation factors VIII, IX, XI, and XIII. However, bleeding and easy bruising, in most instances, relates to fragility of capillaries and compromised vascular integrity. Individuals with Ehlers-Danlos syndrome types 4 and 6 are at risk for aortic dissection and spontaneous rupture of
aortic aneurysms. Surgery should be avoided for patients with Ehlers-Danlos syndrome, as should medications that induce platelet dysfunction.

THROMBOTIC DISORDERS

General Considerations

Although uncommon in children, thrombotic disorders are being recognized with increasing frequency, particularly with heightened physician awareness and improved survival in pediatric intensive care settings. Several clinical conditions have a potential association with thrombotic events in childhood (see the next section Clinical Risk Factors).

Clinical Findings

Initial evaluation of the child who has thrombosis includes an assessment for potential triggering factors, as well as a family history of thrombosis and early cardiovascular or cerebrovascular disease.

A. Clinical Risk Factors

Clinical risk factors are present in more than 90% of children with acute venous thromboembolism (VTE). These conditions include the presence of an indwelling vascular catheter, cardiac disease, infection, trauma, surgery, immobilization, collagen-vascular or chronic inflammatory disease, renal disease, sickle cell anemia, and malignancy. Prospective findings employing serial radiologic evaluation as screening indicate that the risk of VTE is nearly 30% for short-term central venous catheters placed in the internal jugular veins.

Retrospective data suggest that approximately 8% of children with cancer develop symptomatic VTE.

1. Inherited Thrombophilia (Hypercoagulable) States

A. Protein C deficiency—Protein C is a vitamin K–dependent protein that is normally activated by thrombin bound to thrombomodulin and inactivates activated factors V and VIII. In addition, activated protein C promotes fibrinolysis. Two phenotypes of hereditary protein C deficiency exist. Heterozygous individuals with autosomal dominant protein C deficiency often present with VTE as young adults, but the disorder may manifest during childhood or in later adulthood. In mild protein C deficiency, anticoagulant prophylaxis is typically limited to periods of increased prothrombotic risk. Homozygous or compound heterozygous protein C deficiency is rare but phenotypically severe. Affected children generally present within the first 12 hours of life with purpura fulminans (Figure 30–6) and/or VTE.

Prompt protein C replacement by infusion of protein C concentrate or (if unavailable) FFP every 6–12 hours, along with therapeutic heparin administration, is recommended. Subsequent management requires chronic anticoagulation with warfarin, sometimes along with routine protein C concentrate infusion in order to permit lower warfarin dosing. Recurrent VTE is common, especially during periods of subtherapeutic anticoagulation or in the presence of conditions associated with increased prothrombotic risk.

B. Protein S deficiency—Protein S is a cofactor for protein C. Neonates with homozygous protein S deficiency have a course similar to those with homozygous or compound heterozygous protein C deficiency. Lifelong warfarin therapy is indicated in homozygous/severe deficiency, or in heterozygous individuals who have experienced recurrent VTE. Efforts must be made to distinguish these conditions from acquired deficiency, which can be antibody-mediated or secondary to an increase in C4b-binding protein induced by inflammation.

C. Antithrombin deficiency—Antithrombin, which is the most important physiologic inhibitor of thrombin, inhibits activated factors IX, X, XI, and XII. Antithrombin deficiency is transmitted in an autosomal dominant pattern and is associated with VTE, typically with onset in adolescence or young adulthood. Therapy for acute VTE involves replacement with antithrombin concentrate and
therapeutic anticoagulation. The efficiency of heparin may be significantly diminished in the setting of severe antithrombin deficiency and it often requires supplementation of antithrombin via concentrate. Patients with homozygous/severe deficiency or recurrent VTE are maintained on lifelong warfarin.

D. Factor V Leiden mutation—An amino acid substitution in the gene coding for factor V results in factor V Leiden, a factor V polymorphism that is resistant to inactivation by activated protein C. The most common cause of activated protein C resistance in Caucasians, factor V Leiden is present in approximately 5% of the Caucasian population, 20% of Caucasian adults with deep vein thrombosis, and 40%–60% of those with a family history of VTE. VTE occurs in both heterozygous and homozygous individuals. In the former case, thrombosis is typically triggered by a clinical risk factor (or else develops in association with additional thrombophilia traits), whereas in the latter case, it is often spontaneous. Population studies suggest that the risk of incident VTE is increased two- to sevenfold in the setting of heterozygous factor V Leiden, 35-fold among heterozygous individuals taking the oral contraceptives, and 80-fold in those homozygous for factor V Leiden.

E. Prothrombin mutation—The 20210 glutamine to alanine mutation in the prothrombin gene is a relatively common polymorphism in Caucasians that enhances its activation to thrombin. In heterozygous form, this mutation is associated with a two- to threefold increased risk for incident VTE. This mutation also appears to modestly increase the risk for recurrent VTE.

F. Other inherited disorders—Qualitative abnormalities of fibrinogen (dysfibrinogenemias) are usually inherited in an autosomal dominant manner. Most individuals with dysfibrinogenemia are asymptomatic. Some patients experience bleeding, while others develop venous or arterial thrombosis. The diagnosis is suggested by a prolonged thrombin time with a normal fibrinogen concentration. Hyperhomocysteinemia can be an inherited or an acquired condition and is associated with an increased risk for both arterial and venous thromboses. In children, it may also serve as a risk factor for ischemic arterial stroke. Hyperhomocysteinemia is quite uncommon in the setting of dietary folate supplementation (as in the United States) and is observed almost uniquely in cases of renal insufficiency or metabolic disease (eg, homocystinuria). Methylene tetrahydrofolate reductase receptor mutations do not appear to constitute a risk factor for thrombosis in US children if homocysteine is not elevated.

Lipoprotein(a) is a lipoprotein with homology to plasminogen. In vitro studies suggest that lipoprotein(a) may both promote atherothrombosis and inhibit fibrinolysis. Some evidence to date suggests that elevated plasma concentrations of lipoprotein(a) are associated with an increased risk of VTEs and ischemic arterial stroke in children.

Increased factor VIII activity is a risk factor for incident VTE and is common among children with acute VTE. Elevation in factor VIII may persist in the long-term follow-up of these patients, and can be inherited.

2. Acquired Disorders

A. Antiphospholipid antibodies—The development of antiphospholipid antibodies is the most common form of acquired thrombophilia in children. Antiphospholipid antibodies, which include the lupus anticoagulant, anticardiolipin antibodies, and β₂-glycoprotein-1 antibodies (among others) are common in acute childhood VTE. The lupus anticoagulant is demonstrated in vitro by its inhibition of phospholipid-dependent coagulation assays (eg, aPTT and dilute Russell viper venom time), whereas immunologic techniques (eg, enzyme-linked immunosorbent assays) are often used to detect anticardiolipin and β₂-glycoprotein-1 antibodies. Although common in persons with autoimmune diseases such as systemic lupus erythematosus, antiphospholipid antibodies may also develop following certain drug exposures, infection, acute inflammation, and lymphoproliferative diseases. Sometimes VTE and antiphospholipid antibodies may predate other signs of lupus for long periods of time. Viral illness is a common precipitant in children, and in many cases, the inciting infection may be asymptomatic.

If an antiphospholipid antibody persists for 12 weeks following the acute thrombotic event, the diagnosis of this syndrome is confirmed. Optimal duration of anticoagulation in this setting is unclear, such that current pediatric treatment guidelines recommend a 3-month to lifelong course.

B. Deficiencies of intrinsic anticoagulants—Acquired deficiencies of proteins C and S and antithrombin may occur in the clinical context of antibodies (eg, protein S antibodies in acute varicella) or in excessive consumption, including sepsis, DIC, major-vessel or extensive VTE, and post–bone marrow transplant sinusoidal obstruction syndrome (formerly termed hepatic veno-occlusive disease). Pilot studies in children have suggested a possible therapeutic role for antithrombin or protein C concentrates in sepsis-associated DIC (eg, meningococcemia) and severe posttransplant sinusoidal obstruction syndrome.

C. Acute phase reactants—As part of the acute phase response, elevations in plasma fibrinogen concentration, plasma factor VIII, and platelet count may occur, all of which may contribute to an acquired prothrombotic state. Reactive thrombocytosis is rarely associated with VTEs in children when the platelet count is less than 1 million/µL.

B. Symptoms and Signs

Presenting features of thrombosis vary with the anatomic site, extent of vascular involvement, degree of vaso-occlusion, and presence of end-organ dysfunction. The classic presentation of deep venous thrombosis of an upper or lower
extremity is painful acute or subacute extremity swelling, while that for pulmonary embolism commonly involves dyspnea and pleuritic chest pain, and in cerebral sinovenous thrombosis (CSVT) often includes severe or persistent headache, with or without neurologic deficit in otherwise well children. It is not infrequently preceded by sign/symptoms of otitis media progressing to mastoiditis. Arterial thrombosis of the lower extremity (eg, neonatal umbilical artery catheter-associated) as well as vasospasm without identified thrombosis, often manifests with diminished distal pulses and dusky discoloration of the limb.

C. Laboratory Findings

A comprehensive laboratory investigation for thrombophilia (ie, hypercoagulability) is recommended by the International Society on Thrombosis and Haemostasis in order to disclose possible underlying congenital or acquired abnormalities that may affect acute or long-term management. Testing evaluates for intrinsic anticoagulant deficiency (proteins C and S and antithrombin), procoagulant factor excess (eg, factor VIII), proteins and genetic mutations mediating enhanced procoagulant activity or reduced sensitivity to inactivation (antiphospholipid antibodies; factor V Leiden and prothrombin 20210 polymorphisms), biochemical mediators of endothelial damage (homocysteine), and markers or regulators of fibrinolysis (eg, D-dimer, plasminogen activator inhibitor-1, and lipoprotein[a]). Interpretation of procoagulant factor and intrinsic anticoagulant levels should take into account the age dependence of normal values for these proteins. Among these VTE risk factors, antiphospholipid antibodies and elevated levels of homocysteine and lipoprotein[a] have also been demonstrated as risk factors for arterial thrombotic and ischemic events.

D. Imaging

Appropriate radiologic imaging is essential to objectively document the thrombus and to delineate the type (venous vs arterial), occlusiveness, and extent (proximal and distal termini) of thrombosis. Depending on site, typical imaging modalities include compression ultrasound with Doppler, computed tomographic (CT) venography, magnetic resonance venography, and conventional angiography.

Treatment

Current guidelines for the treatment of first-episode VTE in children have been largely based on adult experience and include therapeutic anticoagulation for at least 3 months. During the period of anticoagulation, bleeding precautions should be followed, as previously described (see Treatment under Idiopathic Thrombocytopenic Purpura, earlier); in CVST, presentation with postthrombotic hemorrhage often does not preclude anticoagulant therapy. Initial therapy for acute VTE employs continuous intravenous unfractionated heparin or subcutaneous injections of LMWH) for at least 7 days, monitored by anti-Xa activity level to maintain anticoagulant levels of 0.3–0.7 or 0.5–1.0 IU/mL, respectively. Subsequent extended anticoagulant therapy is given with LMWH or daily oral warfarin, the latter agent monitored by the PT to maintain an international normalized ratio (INR) of 2.0–3.0 (2.5–3.5 in the presence of an antiphospholipid antibody). During warfarin treatment, the INR optimally should be within the therapeutic range for 2 consecutive days before discontinuation of heparin. Warfarin pharmacokinetics are affected by acute illness, numerous medications, and changes in diet, and can necessitate frequent monitoring. In children, warfarin dose is determined by age. LMWH offers the advantage of infrequent need for monitoring but is far more expensive than warfarin. Anatomic contributions to venous stasis (eg, mastoiditis or depressed skull fracture as risk factors for CVST; congenital left iliac vein stenosis in DVT of proximal left lower extremity with May-Thurner anomaly) should be addressed to optimize response to anticoagulation. In cases of limb- or life-threatening VTEs, including major proximal pulmonary embolus, and in cases of progressive VTE despite therapeutic anticoagulation, thrombolytic therapy (eg, tissue-type plasminogen activator) may be considered. A recent cohort study has indicated that initial thrombolytic therapy may also reduce the risk of the postthrombotic syndrome (PTS) in children with veno-occlusive deep venous thrombosis of the proximal limbs in whom adverse prognostic biomarkers (ie, elevated factor VIII and D-dimer levels) are present at diagnosis; however, the safety and efficacy of this approach must be further evaluated in larger studies. In adolescent females, estrogen-containing contraceptives are relatively contraindicated in those with prior VTE, particularly if an additional genetic cause for impairment of protein C pathway is disclosed.

Prognosis

Registries and cohort studies have suggested that recurrent VTE occurs in approximately 10% of children within 2 years. Persistent thrombosis is evident following completion of a standard therapeutic course of anticoagulation in up to 30% of children, with unclear clinical importance. Approximately one in four children with deep venous thrombosis involving the extremities develop post thrombotic syndrome, a condition of venous insufficiency of varying severity characterized by chronic skin changes, edema, and dilated collateral superficial venous formation, and often accompanied by functional limitation (pain with activities or at rest). The presence of homozygous anticoagulant deficiencies, multiple thrombophilia traits, or persistent antiphospholipid antibodies following VTE diagnosis has been associated with increased risk of recurrent VTE, leading to consideration of extended anticoagulation in these instances. Complete veno-occlusion and elevated levels of factor VIII and D-dimer at VTE diagnosis have been identified as prognostic factors for
PTS among children with deep venous thrombosis affecting the limbs. In CSVT failure to provide antithrombotic therapy has been associated with adverse neurologic outcome.

be warranted. Although more commonly associated with acute enlargement, rupture of an enlarged spleen can be seen in more chronic conditions such as Gaucher disease.

ASPLENIA & SPLENECTOMY

Children who lack normal splenic function are at risk for sepsis, meningitis, and pneumonia due to encapsulated bacteria such as pneumococci and H influenzae. Such infections are often fulminant and fatal because of inadequate antibody production and impaired phagocytosis of circulating bacteria.

Congenital asplenia is usually suspected when an infant is born with abnormalities of abdominal viscera and complex cyanotic congenital heart disease. Howell-Jolly bodies are usually present on the peripheral blood smear, and the absence of splenic tissue is confirmed by technetium radionuclide scanning. The prognosis depends on the underlying cardiac lesions, and many children die during the first few months. Prophylactic antibiotics, usually penicillin, and pneumococcal conjugate, Hb, and meningococcal vaccines, are recommended.

The risk of overwhelming sepsis following surgical splenectomy is related to the child’s age and to the underlying disorder. Because the risk is highest when the procedure is performed earlier in life, splenectomy is usually postponed until after age 5 years. The risk of postsplenectomy sepsis is also greater in children with malignancies, thalassemias, and reticuloendothelioses than in children whose splenectomy is performed for ITP, hereditary spherocytosis, or trauma. Prior to splenectomy, children should be immunized against Streptococcus pneumoniae, H influenzae, and Neisseria meningitidis. Additional management should include penicillin prophylaxis and prompt evaluation for fever 38.8°C or above or signs of severe infection.

Children with sickle cell anemia develop functional asplenia during the first year of life, and overwhelming sepsis is the leading cause of early deaths in this disease. Prophylactic penicillin reduces the incidence of sepsis by 84%.

STORAGE & PRESERVATION OF BLOOD & BLOOD COMPONENTS

Whole blood is routinely fractionated into packed red cells, platelets, and FFP or cryoprecipitate for most efficient use of all blood components. The storage conditions and biologic characteristics of the fractions are summarized in Table 30–11. The conditions provide the optimal environment to maintain appropriate recovery, survival, and function, and are different for each blood component. For example, red cells undergo dramatic metabolic changes...

during their 35- to 42-day storage, with a virtual disappearance of 2,3-DPG by day 14 of storage, a decrease in adenosine triphosphate, a gradual loss of intracellular potassium, but in vivo recovery of greater than or equal to 80% transfused cells in red cells by day of storage outdate. Fortunately, these changes are reversed readily in vivo within hours to days after the red cells are transfused. However, in certain clinical conditions, these effects may define the type of components used. For example, blood less than 7–10 days old would be preferred for exchange transfusion in neonates, red cell exchanges in older patients, or replacement of red cells in persons with severe cardiopulmonary disease to ensure adequate oxygen-carrying capacity. Storage time is not an issue when administering transfusions to those with chronic anemia.

If extracellular potassium in older packed red cells may present a problem, one may use blood less than 10 days old, making packed cells out of an older unit of whole blood or washing blood stored as packed cells. Regardless of the blood’s age, greater than 80% of the red cells will circulate after transfusion and approximate normal survival in the circulation.

<td>Contains factor VIII, vWF, fibrinogen, and fibronectin at concentrations greater than those of plasma. Also contains factor XIII, VIII $&gt; 80$ IU/pack, fibrinogen 100-350 mg/pack.</td>
<td>Treatment of acquired or congenital deficiencies of fibrinogen. Useful in making biologic glues that contain fibrinogen. Commercial clotting factor concentrates are the treatment of choice for factor VIII deficiency and vWD because sterilization procedures further reduce the risk of viral transmission.</td>
<td>Same as for fresh frozen plasma. ABO agglutinogens may also be concentrated and can give positive direct agglutination test if not type-specific.</td>
<td>Cryoprecipitate can be given as a rapid infusion. Dose: ½ pack/kg body weight will increase factor VIII level by 80%-100% and fibrinogen by 200-250 mg/dL.</td>
</tr>
</tbody>
</table>
### Platelet concentrates from whole blood donation

- Separated from platelet-rich plasma and stored with gentle agitation at 22-24°C for 5 d. Containers currently in use are plastic and allow for gas exchange; diffusion of CO₂ helps keep pH > 6, a major factor in keeping platelets viable and functional.
- Each unit contains about $5 \times 10^{10}$ platelets. **Survival:** Although there may be some loss with storage, 60%-70% recovery should be achieved, with stored platelets able to correct platelet function test in proportion to the peak counts reached.
- Treatment of thrombocytopenia or platelet function defects. **No cross-match necessary.** Should be ABO type-specific. Other risks as for whole blood. Can be taken during rapid transfusion or as defined by cardiovascular status, not > 4 h. Dose: 10 mL/kg should increase platelet count by at least 50,000/μL.

### Platelet concentrates by apheresis techniques

- Same as random donor units.
- Platelet content is equivalent to 6-10 units of concentrates from whole blood ($3 \times 10^{11}$ platelets); can be made relatively free of leukocytes, which is important for avoiding alloimmunization.
- Same as above, particularly useful in treating patients who have insufficient production and also may have a problem with alloisoimmunization.

### Granulocytes

- Although they may be stored stationary at 22-24°C, transfuse as soon as possible after collection.
- Contains at least $1 \times 10^{10}$ granulocytes, but also platelets and red cells. When donors given 10 mcg/kg G-CSF subcutaneously and 8 mg Decadron orally 12–15 h before collection, yield increases to $> 5 \times 10^{10}$ granulocytes.
- Severely neutropenic individuals (< 500/μL) with poor marrow reserves and suspected bacterial or fungal infections not responding to 48-72 h of parenteral antibiotics. Also in patients with neutrophil dysfunction.
- Same as for platelets. Pulmonary leukostasis reactions. Severe febrile reactions.
- Given in an infusion over 2-4 h. Dose: 1 unit daily for newborns and infants, $1 \times 10^{9}$ granulocytes/kg.

---

**CMV,** cytomegalovirus; **DPG,** diphosphoglycerate; **G-CSF,** granulocyte colony-stimulating factor; **Hct,** hematocrit; **RBC,** red blood cell; **TTP,** thrombotic thrombocytopenic purpura; **vWD,** von Willebrand disease; **vWF,** von Willebrand factor.
Platelets are stored at 22°C for a maximum of 5 days; criteria for 7-day storage are being developed. At the extremes of storage, there should be at least a 60% recovery, a survival time that approximates turnover of fresh autologous platelets, and normalization of the bleeding time or PFA-100 in proportion to the peak platelet count. Frozen components, red cells, FFP, and cryoprecipitate are outdated at 10 years, 1 year, and 1 year, respectively. Frozen red cells retain the same biochemical and functional characteristics as the day they were frozen. FFP contains 80% or more of all of the clotting factors of fresh plasma. Factors VIII and XIII, vWF, and fibrinogen are concentrated in cryoprecipitate.

**PRETRANSFUSION TESTING**

Both the donated blood and the recipient are tested for ABO and Rh(D) antigens and screened for auto- or allo-antibodies in the plasma. The cross-match is required on any component that contains red cells. In the major cross-match, washed donor red cells are incubated with the serum from the patient, and agglutination is detected and graded. The antiglobulin phase of the test may then be performed; Coombs reagent, which will detect the presence of IgG or complement on the surface of the red cells, is added to the mixture, and agglutination is evaluated. In the presence of a negative antibody screen in the recipient, a negative immediate spin cross-match test confirms the compatibility of the blood and antiglobulin phase is not required. Further testing is required if the antibody screen or the cross-match is positive, and blood should not be given until the nature of the reactivity is delineated. An incompatible cross-match is evaluated first with a DAT or Coombs test to detect IgG or complement on the surfaces of the recipient’s red cells. The indirect antiglobulin test is also used to determine the presence of antibodies that will coat red cells or activate complement, and additional studies are completed to define the antibody.

**TRANSFUSION PRACTICE**

**General Rules**

Several rules should be observed in administering any blood component:

1. In final preparation of the component, no solutions should be added to the bag or tubing set except for normal saline (0.9% sodium chloride for injection, USP), ABO-compatible plasma, or other specifically approved expanders. Hypotonic solutions cause hemolysis of red cells, and, if these are transfused, a severe reaction will occur. Any reconstitution should be completed by the blood bank.

2. Transfusion products should be protected from contact with any calcium-containing solution (eg, lactated Ringer); recalcification and reversal of the citrate effect will cause clotting of the blood component.

3. Blood components should not be warmed to a temperature greater than 37°C. If a component is incubated in a water bath, it should be enclosed in a watertight bag to prevent bacterial contamination of entry ports.

4. Whenever a blood bag is entered, the sterile integrity of the system is violated, and that unit should be discarded within 4 hours if left at room temperature or within 24 hours if the temperature is 4–6°C.

5. Transfusions of products containing red cells should not exceed 4 hours. Blood components in excess of what can be infused during this time period should be stored in the blood bank until needed.

6. Before transfusion, the blood component should be inspected visually for any unusual characteristics, such as the presence of flocculent material, hemolysis, or clumping of cells, and mixed thoroughly.

7. The unit and the recipient should be identified properly.

8. The administration set includes a standard 170- to 260-μm filter. Under certain clinical circumstances, an additional microaggregate filter may be used to eliminate small aggregates of fibrin, white cells, and platelets that will not be removed by the standard filter.

9. The patient should be observed during the entire transfusion and especially during the first 15 minutes. With the onset of any adverse symptoms or signs the transfusion should be stopped, an evaluation initiated immediately and the reaction reported promptly to the transfusion service.

10. When cross-match–incompatible red cells or whole blood unit(s) must be given to the patient (as with A1HA), a test dose of 10% of the total volume (not to exceed 50 mL) should be administered over 15–20 minutes; the transfusion is then stopped and the patient observed. If no changes in vital signs or the patient’s condition are noted, the remainder of the volume can be infused carefully.

11. Blood for exchange transfusion in the newborn period may be cross-matched with either the infant’s or the mother’s serum. If the exchange is for hemolysis, 500 mL of whole blood stored for less than 7 days will be adequate. If replacement of clotting factors is a key issue, packed red cells (7 days old) reconstituted with ABO type-specific FFP may be considered. Based on posttransfusion platelet counts, platelet transfusion may be considered. Other problems to be anticipated are acid-base derangements, hypotension, hyperkalemia, hypocalcemia, hypoglycemia, hypothermia, and hypervolemia or hypovolemia.
Choice of Blood Component

Several principles should be considered when deciding on the need for blood transfusion. Indications for blood or blood components must be well defined, and the patient’s medical condition, not just the laboratory results, should be the basis for the decision. Specific deficiencies exhibited by the patient (e.g., oxygen-carrying capacity, thrombocytopenia) should be treated with appropriate blood components and the use of whole blood minimized. Information about specific blood components is summarized in Table 30–11. In general, very little is known about specific indications for blood component transfusion and outcomes. A recent review evaluates what is known and presents fertile areas for investigation (see Josephson, et al).

A. Whole Blood

Whole blood may be used in patients who require replacement of oxygen-carrying capacity and volume. More specifically, it may be considered during massive blood loss, after initial response to replace volume with crystalloid and oxygen carrying capacity. Doses vary depending on volume considerations (see Table 30–11). In acute situations, the transfusion may be completed rapidly to support blood volume.

B. Packed Red Cells

Packed red cells (which include leukocyte-poor, filtered, or frozen deglycerolated products) prepared from whole blood by centrifugal techniques are the appropriate choice for almost all patients with deficient oxygen-carrying capacity. Exact indications will be defined by the clinical setting, the severity of the anemia, the acuity of the condition, and any other factors affecting oxygen transport.

C. Platelets

The decision to transfuse platelets depends on the patient’s clinical condition, the status of plasma phase coagulation, the platelet count, the cause of the thrombocytopenia, and the functional capacity of the patient’s own platelets. In the face of decreased production, clinical bleeding, and platelet counts less than 10,000/μL, the risk of severe, spontaneous bleeding is increased markedly. In the presence of these factors and in the absence heparin-induced thrombocytopenia, TTP, or antibody-mediated thrombocytopenia, transfusion may be considered. Under certain circumstances, especially with platelet dysfunction or treatment that inhibits the procoagulant system, transfusions at higher platelet counts may be necessary.

Transfused platelets are sequestered temporarily in the lungs and spleen before reaching their peak concentrations, 45–60 minutes after transfusion. A significant proportion of the transfused platelets never circulate but remain sequestered in the spleen. This phenomenon results in reduced recovery; under best conditions, only 60%–70% of the transfused platelets are accounted for when peripheral platelet count increments are used as a measure of response.

In addition to cessation of bleeding, two variables indicate the effectiveness of platelet transfusions. The first is platelet recovery, as measured by the maximum number of platelets circulating in response to transfusion. The practical measure is the platelet count at 1 hour after transfusion. In the absence of immune or drastic nonimmune factors that markedly decrease platelet recovery, one would expect a 7000/μL increment for each random donor unit and a 40,000–70,000/μL increment for each single-donor apheresis unit in a large child or adolescent. For infants and small children, 10 mL/kg of platelets will increase the platelet count by at least 50,000/μL. The second variable is the survival of transfused platelets. If the recovery is great enough, transfused platelets will approach a normal half-life in the circulation. In the presence of increased platelet destruction, the life span may be shortened to a few days or a few hours. Frequent platelet transfusions may be required to maintain adequate hemostasis.

A particularly troublesome outcome in patients receiving long-term platelet transfusions is the development of a refractory state characterized by poor (≤ 20%) recovery or no response to platelet transfusion (as measured at 1 hour). Most (70%–90%) of these refractory states result from the development of alloantibodies directed against HLA antigens on the platelet. Platelets have class I HLA antigens, and the antibodies are primarily against HLA A or B determinants. A smaller proportion of these alloantibodies (< 10%) may be directed against platelet-specific alloantigens. The most effective approach to prevent HLA sensitization is to use leukocyte-depleted components (< 5 million leukocytes per unit of packed red cells or per apheresis or 6–10 random donor unit concentrates). For the alloimmunized, refractory patient, the best approach is to provide HLA-matched platelets for transfusion. Reports have suggested that platelet cross-matching procedures using HLA-matched or unmatched donors may be helpful in identifying platelet concentrates most likely to provide an adequate response.

D. Fresh Frozen Plasma

The indication for fresh frozen plasma (FFP) is replacement of plasma coagulation factors in clinical situations in which a deficiency of one or more clotting factors exists and associated bleeding manifestations are present. In some hereditary factor deficiencies, such as factor VIII deficiency or vWD, commercially prepared concentrates contain these factors in higher concentrations and, because of viral inactivation, impose less infectious risk and are more appropriate than...

<th>Signs and Symptoms</th>
<th>Management</th>
</tr>
</thead>
<tbody>
<tr>
<td>Acute hemolytic transfusion reaction</td>
<td>Preformed alloantibodies (most commonly to ABO) and infrequently autoantibodies cause rapid intravascular hemolysis of transfused cells with activation of clotting (DIC), activation of inflammatory mediators, and acute renal failure.</td>
<td>Fever, chills, nausea, chest pain, back pain, pain at transfusion site, hypotension, dyspnea, oliguria, hemoglobinuria.</td>
<td>The risk of this type of reaction overall is low (1:70,000–1:30,000), but the mortality rate is high (up to 40%). Stop the transfusion; maintain renal output with intravenous fluids and diuretics (furosemide or mannitol); treat DIC with heparin; and institute other appropriate supportive measures.</td>
</tr>
<tr>
<td>Delayed hemolytic transfusion reaction</td>
<td>Formation of alloantibodies after transfusion and resultant destruction of transfused red cells, usually by extravascular hemolysis.</td>
<td>Jaundice, anemia. A small percentage may develop chronic hemolysis.</td>
<td>Detection, definition, and documentation (for future transfusions). Supportive care. Risk, &lt;5% of transfused patients may develop alloantibody; hemolysis, 1:11,000–1:2500.</td>
</tr>
<tr>
<td>Febrile reactions</td>
<td>Usually caused by leukoagglutinins in recipient, cytokines, or other biologically active compounds.</td>
<td>Fever. May also involve chills.</td>
<td>Supportive. Leukocyte-reduced products decrease reactions. Risk per transfusion, 1:100 transfusions.</td>
</tr>
<tr>
<td>Allergic reactions</td>
<td>Most causes not identified. In IgA-deficient individuals, reaction occurs as a result of antibodies to IgA.</td>
<td>Itching, hives, and occasionally chills and fever. In severe reactions, may see signs of anaphylaxis: dyspnea, pulmonary edema.</td>
<td>Mild to moderate reactions: diphenhydramine. More severe reactions: epinephrine subcutaneously and steroids intravenously. Risk for mild to moderate allergic reactions, 1:100. Severe anaphylactic reactions, 1:50,000–1:20,000.</td>
</tr>
<tr>
<td>Transfusion-related acute lung injury</td>
<td>Acute lung injury occurring within 6 h after transfusion. Two sets of factors interact to produce the syndrome. Patient factors: infection, surgery, cytokine therapy. Blood component factors: lipids, antibodies, cytokines. Two groups of factors interact during transfusion to result in lung injury indistinguishable from ARDS.</td>
<td>Tachypnea, dyspnea, hypoxia. Diffuse interstitial markings. Cardiac evaluation normal.</td>
<td>May consider younger products: packed red blood cells ≤ 2 wk, platelets ≤ 3 d, washing components to prevent syndrome. Management: supportive care. Risk, 1:2000–1:3000 per transfusion. Current preventive procedures include avoiding donors at risk for alloimmunization; use of male-only FFP or white blood cell antibody-negative apheresis FFP or platelet products.</td>
</tr>
<tr>
<td>Dilutional coagulopathy</td>
<td>Massive blood loss and transfusion with replacement with fluids or blood components and deficient clotting factors.</td>
<td>Bleeding.</td>
<td>Replacement of clotting factors or platelets with appropriate blood components.</td>
</tr>
<tr>
<td>Bacterial contamination</td>
<td>Contamination of units results in growth of bacteria or production of clinically significant levels of endotoxin.</td>
<td>Chills, high fever, hypotension, other symptoms of sepsis or endotoxemia.</td>
<td>Stop transfusion; make aggressive attempts to identify organism; provide vigorous support. Sepsis in 1:500,000–1:75,000</td>
</tr>
<tr>
<td>Graft-versus-host disease</td>
<td>Lymphocytes from donor transfused in an immunoincompetent host.</td>
<td>Syndrome can involve a variety of organs, usually skin, liver, gastrointestinal tract, and bone marrow.</td>
<td>Rare. Preventive management: irradiation (&gt;1500 cGy) of cellular blood components transfused to individuals with congenital or acquired immunodeficiency syndromes, intrauterine transfusion, very premature infants, and when donors are relatives of the recipient.</td>
</tr>
<tr>
<td>Iron overload</td>
<td>There is no physiologic mechanism to excrete excess iron. Target organs include liver, heart, and endocrine organs. In patients receiving red cell transfusions over long periods of time, there is an increase in iron burden.</td>
<td>Signs and symptoms of dysfunctional organs affected by the iron.</td>
<td>Significant risk with chronic transfusions. Treated with chronic administration of iron chelator such as deferoxamine given intravenously or Exjade given orally.</td>
</tr>
</tbody>
</table>

ARDS, adult respiratory distress syndrome; DIC, disseminated intravascular coagulation; FFP, fresh frozen plasma.
plasma. Treatment with FFP is indicated for decreased liver production of clotting factors or generalized consumption (DIC) when INR is greater than 1.5.

E. Cryoprecipitate

This component may be used for acquired or congenital disorders of hypofibrinogenemia or a fibrinogenemia. Although cryoprecipitate is a rich source for factor VIII or vWF, commercial concentrates that contain these factors are more appropriate (see preceding section). The dose given depends on the protein to be replaced. Cryoprecipitate can be given in a rapid transfusion over 30–60 minutes and is currently under investigation.

F. Granulocytes

With better supportive care over the past 20 years, the need for granulocytes in neutropenic patients with severe bacterial infections has decreased. Indications still remain for severe bacterial or fungal infections unresponsive to vigorous medical therapy in either newborns or older children with bone marrow failure, or patients with neutrophil dysfunction. Newer mobilization schemes using G-CSF and steroids in donors result in granulocyte collections with at least 50 billion neutrophils. This may provide a better product for patients requiring granulocyte support.

G. Apheresis Products and Procedures

Apheresis equipment allows one or more blood components to be collected while the rest are returned to the donor. Apheresis platelet concentrates, which have as many platelets as 6–10 units of platelet concentrates from whole blood donations, are one example; granulocytes are another. Apheresis techniques can also be used to collect hematopoietic stem cells that have been mobilized into the blood by cytokines (eg, G-CSF) given alone or after chemotherapy or mononuclear cells for immunotherapy. These stem cells are used for allogeneic or autologous bone marrow transplantation. Blood cell separators can be used for the collection of single-source plasma or removal of a blood component that is causing disease. Examples include red cell exchange in sickle cell disease and plasmapheresis in Goodpasture syndrome or in Guillain-Barré syndrome.

Adverse Effects

The noninfectious complications of blood transfusions are outlined in Table 30–12. Most complications present a significant risk to the recipient.

REFERENCES

Neoplastic Disease

Each year approximately 150 out of every 1 million children younger than age 20 years are diagnosed with cancer. For children between the ages of 1 and 20 years, cancer is the fourth leading cause of death, behind unintentional injuries, homicides, and suicides. However, combined-modality therapy, including surgery, chemotherapy, and radiation therapy, has improved survival dramatically, such that the overall 5-year survival rate of pediatric malignancies is now greater than 75%. It is estimated that by the year 2020, 1 in 600 adults will be a survivor of childhood cancer.

Because pediatric malignancies are rare, cooperative clinical trials have become the mainstay of treatment planning and therapeutic advances. The Children’s Oncology Group (COG), representing the amalgamation of four prior pediatric cooperative groups (Children’s Cancer Group, Pediatric Oncology Group, Intergroup Rhabdomyosarcoma Study Group, and the National Wilms Tumor Study Group), offers current therapeutic protocols and strives to answer important treatment questions. A child or adolescent newly diagnosed with cancer should be enrolled in a cooperative clinical trial whenever possible. Because many protocols are associated with significant toxicities, morbidity, and potential mortality, treatment of children with cancer should be supervised by a pediatric oncologist familiar with the hazards of treatment, preferably at a multidisciplinary pediatric cancer center.

Advances in molecular genetics, cell biology, and tumor immunology have contributed and are crucial to the continued understanding of pediatric malignancies and their treatment. Continued research into the biology of tumors will lead to the identification of targeted therapy for specific tumor types with, it is hoped, fewer systemic effects.

Research in supportive care areas, such as prevention and management of infection, pain, and emesis, has improved the survival and quality of life for children undergoing cancer treatment. Long-term studies of childhood cancer survivors are yielding information that provides a rationale for modifying future treatment regimens to decrease morbidity. A guide for caring for childhood cancer survivors is now available to medical providers as well as families and details suggested examinations and late effects by type of chemotherapy received.

MAJOR PEDIATRIC NEOPLASTIC DISEASES

ACUTE LYMPHOBLASTIC LEUKEMIA

General Considerations

Acute lymphoblastic leukemia (ALL) is the most common malignancy of childhood, accounting for about 25% of all cancer diagnoses in patients younger than age 15 years. The worldwide incidence of ALL is about 1:25,000 children per year, including 3000 children per year in the United States. The peak age at onset is 4 years; 85% of patients are diagnosed between ages 2 and 10 years. Children with Down syndrome have a 14-fold increase in the overall rate of leukemia.

ALL results from uncontrolled proliferation of immature lymphocytes. Its cause is unknown, and genetic factors may play a role. Leukemia is defined by the presence of more than 25% malignant hematopoietic cells (blasts) in the bone marrow aspirate. Leukemic blasts from the majority of cases of childhood ALL have an antigen on the cell surface called the common ALL antigen (CALLA). These blasts derive from B-cell precursors early in their development, called B-precursor ALL. Less commonly, lymphoblasts are of T-cell origin or of mature B-cell origin. Over 70% of children receiving aggressive combination chemotherapy and early
presymptomatic treatment to the central nervous system (CNS) are now cured of ALL.

**Clinical Findings**

**A. Symptoms and Signs**

Presenting complaints of patients with ALL include those related to decreased bone marrow production of red blood cells (RBCs), white blood cells (WBCs), or platelets and to leukemic infiltration of extramedullary (outside bone marrow) sites. Intermittent fevers are common, as a result of either cytokines induced by the leukemia itself or infections secondary to leukopenia. Many patients present due to bruising or pallor. About 25% of patients experience bone pain, especially in the pelvis, vertebral bodies, and legs.

Physical examination at diagnosis ranges from virtually normal to highly abnormal. Signs related to bone marrow infiltration by leukemia include pallor, petechiae, and purpura. Hepatomegaly and/or splenomegaly occur in over 60% of patients. Lymphadenopathy is common, either localized or generalized to cervical, axillary, and inguinal regions. The testes may occasionally be unilaterally or bilaterally enlarged secondary to leukemic infiltration. Superior vena cava syndrome is caused by mediastinal adenopathy compressing the superior vena cava. A prominent venous pattern develops over the upper chest from collateral vein enlargement. The neck may feel full from venous engorgement. The face may appear plethoric, and the periorbital area may be edematous. A mediastinal mass can cause tachypnea, orthopnea, and respiratory distress. Leukemic infiltration of cranial nerves may cause cranial nerve palsies with mild nuchal rigidity. The optic fundi may show exudates of leukemic infiltration and hemorrhage from thrombocytopenia. Anemia can cause a flow murmur, tachycardia, and, rarely, congestive heart failure.

**B. Laboratory Findings**

A complete blood count (CBC) with differential is the most useful initial test because 95% of patients with ALL have a decrease in at least one cell type (single cytopenia): neutropenia, thrombocytopenia, or anemia with most patients having a decrease in at least two blood cell lines. The WBC count is low or normal (≥ 10,000/μL) in 50% of patients, but the differential shows neutropenia (absolute neutrophil count < 1000/μL) along with a small percentage of blasts amid normal lymphocytes. In 30% of patients the WBC count is between 10,000/μL and 50,000/μL; in 20% of patients it is over 50,000/μL, occasionally higher than 300,000/μL. Blasts are usually readily identifiable on peripheral blood smears from patients with elevated WBC counts. Peripheral blood smears also show abnormalities in RBCs, such as teardrops. Most patients with ALL have decreased platelet counts (< 150,000/μL) and decreased hemoglobin (< 11 g/dL) at diagnosis. In approximately 1% of patients diagnosed with ALL, CBCs and peripheral blood smears are entirely normal but patients have bone pain that leads to bone marrow examination. Serum chemistries, particularly uric acid and lactate dehydrogenase (LDH), are often elevated at diagnosis as a result of cell breakdown.

The diagnosis of ALL is made by bone marrow examination, which shows a homogeneous infiltration of leukemic blasts replacing normal marrow elements. The morphology of blasts on bone marrow aspirate can usually distinguish ALL from acute myeloid leukemia (AML). Lymphoblasts are typically small, with cell diameters of approximately two erythrocytes. Lymphoblasts have scant cytoplasm, usually without granules. The nucleus typically contains no nucleoli or one small, indistinct nucleolus. Immunophenotyping of ALL blasts by flow cytometry helps distinguish precursor B-cell ALL from T-cell ALL or AML. Histochemical stains specific for myeloblastic and monoblastic leukemias (myeloperoxidase and nonspecific esterase) distinguish ALL from AML. About 5% of patients present with CNS leukemia, which is defined as a cerebrospinal fluid (CSF) WBC count greater than 5/μL with blasts present on cytocentrifuged specimen.

**C. Imaging**

Chest radiograph may show mediastinal widening or an anterior mediastinal mass and tracheal compression secondary to lymphadenopathy or thymic infiltration, especially in T-cell ALL. Abdominal ultrasound may show kidney enlargement from leukemic infiltration or uric acid nephropathy as well as intra-abdominal adenopathy. Plain radiographs of the long bones and spine may show demineralization, periosteal elevation, growth arrest lines, or compression of vertebral bodies. Although these findings may suggest leukemia, they are not diagnostic.

**Differential Diagnosis**

The differential diagnosis, based on the history and physical examination, includes chronic infections by Epstein-Barr virus (EBV) and cytomegalovirus (CMV), causing lymphadenopathy, hepatosplenomegaly, fevers, and anemia. Prominent petechiae and purpura suggest a diagnosis of immune thrombocytopenic purpura. Significant pallor could be caused by transient erythroblastopenia of childhood, autoimmune hemolytic anemias, or aplastic anemia. Fevers and joint pains, with or without hepatosplenomegaly and lymphadenopathy, suggest juvenile rheumatoid arthritis (JRA). The diagnosis of leukemia usually becomes straightforward once the CBC reveals multiple cytopenias and leukemic blasts. Serum LDH levels may help distinguish JRA from leukemia, as the LDH is usually normal in JRA.
An elevated WBC count with lymphocytosis is typical of pertussis; however, in pertussis the lymphocytes are mature, and neutropenia is rarely associated.

**Treatment**

**A. Specific Therapy**

Intensity of treatment is determined by specific prognostic features present at diagnosis, the patient’s response to therapy, and specific biologic features of the leukemia cells. The majority of patients with ALL are enrolled in clinical trials designed by clinical groups and approved by the National Cancer Institute; the largest group is COG (Children’s Oncology Group). The first month of therapy consists of induction, at the end of which over 95% of patients exhibit remission on bone marrow aspirates by morphology. The drugs most commonly used in induction include oral prednisone or dexamethasone, intravenous vincristine, daunorubicin, intramuscular or intravenous asparaginase, and intrathecal methotrexate.

Consolidation is the second phase of treatment, during which intrathecal chemotherapy along with continued systemic therapy and sometimes cranial radiation therapy are given to kill lymphoblasts “hiding” in the meninges. Several months of intensive chemotherapy follows consolidation, often referred to as intensification. This intensification has led to improved survival in pediatric ALL.

Maintenance therapy can include daily oral mercaptopurine, weekly oral methotrexate, and, often, monthly pulses of intravenous vincristine and oral prednisone or dexamethasone. Intrathecal chemotherapy, either with methotrexate alone or combined with cytarabine and hydrocortisone, is usually given every 2–3 months.

Chemotherapy has significant potential side effects. Patients need to be monitored closely to prevent drug toxicities and to ensure early treatment of complications. The duration of treatment ranges between 2.2 years for girls and 3.2 years for boys in COG trials. Treatment for ALL is tailored to prognostic, or risk, groups. A child aged 1–9 years with a WBC count below 50,000/μL at diagnosis of pre B ALL and without poor biologic features [(t(9;22) or an 11q23 rearrangement)] is considered to be at “standard risk” and receives less intensive therapy than a “high-risk” patient who has a WBC count at diagnosis over 50,000/μL or is 10 years of age or greater. An infant less than 1 year at diagnosis would be considered very high risk and receive even more intensive chemotherapy. Also important is the patient’s response to treatment determined by minimal residual disease (MRD) monitoring. This risk-adapted treatment approach has significantly increased the cure rate among patients with less favorable prognostic features by allowing for early intensification while minimizing treatment-related toxicities in those with favorable features. Bone marrow relapse is usually heralded by an abnormal CBC, either during treatment or following completion of therapy.

The CNS and testes are sanctuary sites of extramedullary leukemia. Currently, about one-third of all ALL relapses are isolated to these sanctuary sites. Systemic chemotherapy does not penetrate these tissues as well as it penetrates other organs. Thus, presymptomatic intrathecal chemotherapy is a critical part of ALL treatment, without which many more relapses would occur in the CNS, with or without bone marrow relapse. The majority of isolated CNS relapses are diagnosed in an asymptomatic child at the time of routine intrathecal injection, when CSF cell count and differential shows an elevated WBC with leukemic blasts. Occasionally, symptoms of CNS relapse develop: headache, nausea and vomiting, irritability, nuchal rigidity, photophobia, changes in vision, and cranial nerve palsies. Currently, testicular relapse occurs in less than 5% of boys. The presentation of testicular relapse is usually unilateral painless testicular enlargement, without a distinct mass. Routine follow-up of boys both on and off treatment includes physical examination of the testes.

Bone marrow transplantation, now called hematopoietic stem cell transplantation (HSCT), is rarely used as initial treatment for ALL, because most patients are cured with chemotherapy alone. Patients whose blasts contain certain chromosomal abnormalities, such as t(9;22) or hypodiploidy (< 44 chromosomes), and patients with a very slow response to therapy may have a better cure rate with early HSCT from a human leukocyte antigen (HLA)-DR–matched sibling donor, or perhaps a matched unrelated donor, than with intensive chemotherapy alone. HSCT cures about 50% of patients who relapse, provided that a second remission is achieved with chemotherapy before transplant. Children who relapse more than 1 year after completion of chemotherapy (late relapse) may be cured with intensive chemotherapy without HSCT.

Several new biologic agents, including tyrosine kinase inhibitors and immunotoxins, are currently in various stages of research, development, and in chemotherapeutic trials. Some of these therapies may prove relevant for future treatment of poor risk or relapsed ALL.

Several years ago, Imatinib, a tyrosine kinase inhibitor (TKI), directed against the Philadelphia chromosome (Ph+) protein product, was combined in a backbone of intensive ALL therapy for Ph+ ALL in pediatric patients. The preliminary results of this trial showed a 3-year event-free survival (EFS) of 78% compared to about 50% in historical controls. An ongoing trial for COG in Ph+ ALL is incorporating a newer, more targeted TKI, Dasatinib, into a very similar intensive chemotherapy background with the goal of improving EFS further for this select group of patients. As more is understood about the biology of ALL, further therapy will likely include more of these targeted agents.
B. Supportive Care

Tumor lysis syndrome, which consists of hyperkalemia, hyperuricemia, hyperphosphatemia, should be anticipated when treatment is started. Maintaining brisk urine output with intravenous fluids plus/minus alkalinization of urine with intravenous sodium bicarbonate, and treating with oral allopurinol are appropriate steps in managing tumor lysis syndrome. Rasburicase is indicated for severe tumor lysis syndrome with initial high uric acid values or high WBC at presentation. Serum levels of potassium, phosphorus, and uric acid should be monitored. If superior vena caval or superior mediastinal syndrome is present, general anesthesia is contraindicated temporarily and until there has been some decrease in the mass. If hyperleukocytosis (WBC count > 100,000/μL) is accompanied by hyperviscosity with symptoms of respiratory distress and/or mental status changes, leukaphoresis may be indicated to rapidly reduce the number of circulating blasts and minimize the potential thrombotic or hemorrhagic CNS complications. Throughout the course of treatment, all transfused blood and platelet products should be irradiated to prevent graft-versus-host disease from the transfused lymphocytes. Whenever possible, blood products should be leukodepleted to minimize CMV transmission, transfusion reactions, and sensitization to platelets.

Due to the immunocompromised state of the patient with ALL, bacterial, fungal, and viral infections are serious and can be life-threatening or fatal. During the course of treatment, fever (temperature = 38.3°C) and neutropenia (absolute neutrophil count < 500/μL) require prompt assessment, blood cultures from each lumen of a central line, and prompt treatment with empiric broad-spectrum antibiotics. Patients receiving ALL treatment must receive prophylaxis against Pneumocystis jiroveci (formerly Pneumocystis carinii). Trimethoprim–sulfamethoxazole given twice each day on 2 or 3 consecutive days per week is the drug of choice. Patients who are nonimmune to varicella are at risk for very serious—even fatal—infection. Such patients should receive varicella-zoster immune globulin (VZIG) within 72 hours after exposure and treatment with intravenous acyclovir for active infection.

Prognosis

Cure rates depend on specific prognostic features present at diagnosis, biologic features of the leukemic blast, and the response to therapy. Two of the most important features are WBC count and age. Children aged 1–9 years whose diagnostic WBC count is less than 50,000/μL, standard risk ALL, have an EFS in the 90% range, while children 10 years of age or older have an EFS of approximately 88%. Minimal residual disease (MRD) measurements are now frequently used to determine both the rapidity of response as well as the depth of remission attained at the end of induction (first 4–6 weeks of therapy). Patients with very low levels of MRD at the end of induction will likely have a superior EFS as compared to other patients with similar initial risk factors but a higher MRD level. On the flip side, by identifying patients with higher MRD at end induction, more intensified therapy can be delivered in order to reduce the MRD and thus, improve the EFS.

Certain chromosomal abnormalities present in the leukemic blasts at diagnosis influence prognosis. Patients with t(9;22), the Philadelphia chromosome, had a poor chance of cure in the past but as discussed earlier in this chapter, now have improved outcome with the incorporation of a directed TKI. Likewise, infants younger than age 6 months with t(4;11) have a poor chance of cure with conventional chemotherapy. In contrast, patients whose blasts are hyperdiploid (containing > 50 chromosomes instead of the normal 46) with trisomies of chromosomes 4, and 10, and patients whose blasts have a t(12;21) and ETV6-AML1 rearrangement have a greater chance of cure, approaching 95%–97% EFS, than do children without these characteristics.
is responsible for at least one-third of deaths from leukemia in children and teenagers. Congenital conditions associated with an increased risk of AML include Diamond-Blackfan anemia; neurofibromatosis; Down syndrome; Wiskott-Aldrich, Kostmann, and Li-Fraumeni syndromes; as well as chromosomal instability syndromes such as Fanconi anemia. Acquired risk factors include exposure to ionizing radiation, cytotoxic chemotherapeutic agents, and benzenes. However, the vast majority of patients have no identifiable risk factors. Historically, the diagnosis of AML was based almost exclusively on morphology and immunohistochemical staining of the leukemic cells. AML has eight subtypes (M0–M7) according to the French-American-British (FAB) classification (Table 31–1). Immunophenotypic, cytogenetic, and molecular analyses are increasingly important in confirming the diagnosis of AML and subclassifying it into biologically distinct subtypes that have therapeutic and prognostic implications. Recently the World Health Organization (WHO) classification was published to describe AML as AML with recurrent genetic abnormalities with a list of genetic abnormalities sufficient to diagnose AML and then AML not otherwise specified with morphologic descriptions of AML including similar to the FAB classification. Cytogenetic clonal abnormalities occur in 80% of patients with AML and are often predictive of outcome.

### Clinical Findings

The clinical manifestations of AML commonly include anemia (44%), thrombocytopenia (33%), and neutropenia (69%). Symptoms may be few and innocuous or may be life-threatening. The median hemoglobin value at diagnosis is 7 g/dL, and platelets usually number fewer than 50,000/μL. Frequently the absolute neutrophil count is under 1000/μL, although the total WBC count is over 100,000/μL in 25% of patients at diagnosis.

Hyperleukocytosis may be associated with life-threatening complications. Venous stasis and sludging of blasts in small vessels cause hypoxia, hemorrhage, and infarction, most notably in the lung and CNS. This clinical picture is a medical emergency requiring rapid intervention, such as leukopheresis, to decrease the leukocyte count. CNS leukemia is present in 5%–15% of patients at diagnosis, a higher rate of initial involvement than in ALL. Certain subtypes, such as M4 and M5, have a higher likelihood of meningeal infiltration than do other subtypes. Additionally, clinically significant

CNS, central nervous system; FAB, French-American-British classification.
coagulopathy may be present at diagnosis in patients with M3, M4, or M5 subtypes. This problem manifests as bleeding or an abnormal disseminated intravascular coagulation screen and should be at least partially corrected prior to initiation of treatment, which may transiently exacerbate the coagulopathy.

Treatment

A. Specific Therapy

AML is less responsive to treatment than ALL and requires more intensive chemotherapy. Toxicities from therapy are common and likely to be life-threatening; therefore, treatment should be undertaken only at a tertiary pediatric oncology center.

Current AML protocols rely on intensive administration of anthracyclines, cytarabine, and etoposide for induction of remission. After remission is obtained, patients who have a matched sibling donor undergo allogeneic HSCT, while those without an appropriate related donor are treated with additional cycles of aggressive chemotherapy for a total of 4–5 cycles. Inv16 and (t;8;21) herald a more responsive subtype of AML. In patients with a rapid response to induction chemotherapy, intensive chemotherapy alone may be curative in patients whose blasts harbor these cytogenetic abnormalities. Additional recognized genetic risk factors that carry a poor outcome for children with AML include monosomy 7 and FLT3 internal tandem duplications (ITD). HSCT is recommended for all these patients, using either a related or unrelated donor. Trials with risk grouping are ongoing as more is understood about the varying biologic factors.

The biologic heterogeneity of AML is becoming increasingly important therapeutically. The M3 subtype, associated with t(15;17) demonstrated either cytogenetically or molecularly, is currently treated with all trans-retinoic acid in addition to chemotherapy with high-dose cytarabine and daunorubicin. All trans-retinoic acid leads to differentiation of promyelocytic leukemia cells and can induce remission, but cure requires conventional chemotherapy as well. The use of arsenic trioxide has also been investigated in the treatment of this subtype of AML with favorable results. This subtype has an increased event-free survival over other AML subtypes.

Another biologically distinct subtype of AML occurs in children with Down syndrome, M7, or megakaryocytic AML. Using less intensive treatment, remission induction rate and overall survival of these children are dramatically superior to non–Down syndrome children with AML. It is important that children with Down syndrome receive appropriate treatment specifically designed to be less intensive due to their increased rate of toxicity with chemotherapeutic agents.

As with ALL, newer biologic agents with more specific targeting are available and undergoing clinical trails.

One such agent, sorafenib, appears to be active against AML with Flt3 ITDs. Combining sorafenib with AML therapy has been useful in relapsed disease and is now being studied in to upfront trials.

Clofarabine, a newer nucleoside analogue, also has activity in AML and is currently undergoing trials in relapsed and refractory patients with promising results.

B. Supportive Care

Tumor lysis syndrome rarely occurs during induction treatment of AML. Nevertheless, when the diagnostic WBC cell count is greater than 100,000/μL or significant adenopathy or organomegaly is present, one should maintain brisk urine output, and follow potassium, uric acid, and phosphorous laboratory values closely. Hyperleukocytosis (WBC > 100,000/μL) is a medical emergency and, in a symptomatic patient, requires rapid intervention such as leukopheresis to rapidly decrease the number of circulating blasts and thereby decrease hyperviscosity. Delaying transfusion of packed RBCs until the WBC can be decreased to below 100,000/μL avoids exacerbating hyperviscosity. It is also important to correct the coagulopathy commonly associated with M3, M4, or M5 subtypes prior to beginning induction chemotherapy. As with the treatment of ALL, all blood products should be irradiated and leukodepleted; Pneumocystis prophylaxis must be administered during treatment and for several weeks afterward; and patients not immune to varicella must receive VZIG within 72 hours of exposure and prompt treatment with intravenous acyclovir for active infection.

Onset of fever (temperature ≥ 38.3°C) or chills associated with neutropenia requires prompt assessment, blood cultures from each lumen of a central venous line, other cultures such as throat or urine as appropriate and prompt initiation of broad-spectrum intravenous antibiotics. Infections in this population of patients can rapidly become life-threatening. Because of the high incidence of invasive fungal infections, there should be a low threshold for initiating antifungal therapy. Filgrastim (granulocyte colony-stimulating factor) may be used to stimulate granulocyte recovery during the treatment of AML and results in shorter periods of neutropenia and hospitalization. It must be stressed that the supportive care for this group of patients is as important as the leukemia-directed therapy and that this treatment should be carried out only at a tertiary pediatric cancer center.

Prognosis

Published results from various centers show a 50%–60% survival rate at 5 years following first remission for patients who do not have matched sibling hematopoietic stem cell donors. Patients with matched sibling donors fare slightly better, with 5-year survival rates of 60%–70% after allogeneic HSCT.

As treatment becomes more sophisticated, outcome is increasingly related to the subtype of AML. Currently, AML
in patients with t(8;21), t(15;17), inv 16, or Down syndrome has the most favorable prognosis, with 65%–75% long-term survival using modern treatments, including chemotherapy alone. The least favorable outcome occurs in AML patients with monosomy 7 or 5, 7q, 5q−, 11q23 cytogenetic abnormalities, or FLT 3 mutations or ITD.

MYELOPROLIFERATIVE DISEASES

Myeloproliferative diseases in children are relatively rare. They are characterized by ineffective hematopoiesis that results in excessive peripheral blood counts. The three most important types are chronic myelogenous leukemia (CML), which accounts for less than 5% of the childhood leukemias, transient myeloproliferative disorder in children with Down syndrome, and juvenile myelomonocytic leukemia (Table 31–2).

1. Chronic Myelogenous Leukemia

General Considerations

CML with translocation of chromosomes 9 and 22 (the Philadelphia chromosome, Ph+) is identical to adult Ph+CML. Translocation 9;22 results in the fusion of the BCR gene on chromosome 22 and the ABL gene on chromosome 9. The resulting fusion protein is a constitutively active tyrosine kinase that interacts with a variety of effector proteins and allows for deregulated cellular proliferation, decreased adhesion of cells to the bone marrow extracellular matrix, and resistance to apoptosis. The disease usually progresses within 3 years to an accelerated phase and then to a blast crisis. It is generally accepted that Ph+ cells have an increased susceptibility to the acquisition of additional molecular changes that lead to the accelerated and blast phases of disease.

Clinical Findings

Patients with CML may present with nonspecific complaints similar to those of acute leukemia, including bone pain, fever, night sweats, and fatigue. However, patients can also be asymptomatic. Patients with a total WBC count of more than 100,000/μL may have symptoms of leukostasis, such as dyspnea, priapism, or neurologic abnormalities. Physical findings may include fever, pallor, ecchymoses, and hepatosplenomegaly. Anemia, thrombocytosis, and leukocytosis are frequent laboratory findings. The peripheral smear is usually diagnostic, with a characteristic predominance of myeloid cells in all stages of maturation, increased basophils and relatively few blasts.

CML, chronic myelogenous leukemia; DS, Down syndrome; JMML, juvenile myelomonocytic leukemia; TMD, transient myeloproliferative disorder.
**Treatment & Prognosis**

Historically, hydroxyurea or busulfan has been used to reduce or eliminate Ph+ cells and HSCT was the only consistently curative intervention. Reported survival rates for patients younger than age 20 years transplanted in the chronic phase from matched-related donors are 70%–80%. Unrelated stem cell transplants result in survival rates of 50%–65%.

The understanding of the molecular mechanisms involved in the pathogenesis of CML has led to the rational design of molecularly targeted therapy. Imatinib mesylate (Gleevec) is a tyrosine kinase inhibitor that has had dramatic success in the treatment of CML, with most adults and children achieving cytogenetic remission. There are now newer, more targeted TKIs including dasatinib, erlotinib, nilotinib, and ponatinib. These medications in adults have an increased incidence of molecular remissions and may be all that is required for long-term survival in adults. The durability of the remission for children with TKIs therapy alone is unclear but is now the accepted upfront therapy.

2. Transient Myeloproliferative Disorder

Transient myeloproliferative disorder is unique to patients with trisomy 21 or mosaicism for trisomy 21. It is characterized by uncontrolled proliferation of blasts, usually of megakaryocytic origin, during early infancy and spontaneous resolution. The pathogenesis of this process is not well understood, although mutations in the GATA1 gene have been recently implicated as initial events.

Although the true incidence is unknown, it is estimated to occur in up to 10% of patients with Down syndrome. Despite the fact that the process usually resolves by 3 months of age, organ infiltration may cause significant morbidity and mortality.

Patients can present with hydrops fetalis, pericardial or pleural effusions, or hepatic fibrosis. More frequently, they are asymptomatic or only minimally ill. Therefore, treatment is primarily supportive. Patients without symptoms are not treated, and those with organ dysfunction receive low doses of chemotherapy or leukaphoresis (or both) to reduce peripheral blood blast counts. Although patients with transient myeloproliferative disorder have apparent resolution of the process, approximately 30% go on to develop acute megakaryoblastic leukemia (AML M7) within 3 years.

3. Juvenile Myelomonocytic Leukemia

Juvenile myelomonocytic leukemia (JMML) accounts for approximately one-third of the myelodysplastic and myeloproliferative disorders in childhood. Patients with neurofibromatosis type 1 (NF-1) are at higher risk of JMML than the general population. It typically occurs in infants and very young children and is occasionally associated with monosomy 7 or a deletion of the long arm of chromosome 7.

Patients with JMML present similarly to those with other hematopoietic malignancies, with lymphadenopathy, hepatosplenomegaly, skin rash, or respiratory symptoms. Patients may have stigmata of NF-1 with neurofibromas or café au lait spots. Laboratory findings include anemia, thrombocytopenia, leukocytosis with monocytosis, and elevated fetal hemoglobin.

The results of chemotherapy for children with JMML have been disappointing, with estimated survival rates of less than 30%. Approximately 40%–45% of patients are projected to survive long term using HSCT, although optimizing conditioning regimens and donor selection may improve these results.

**BRAIN TUMORS**

**General Considerations**

The classic triad of morning headache, vomiting, and papilledema is present in fewer than 30% of children at presentation. School failure and personality changes are common in older children. Irritability, failure to thrive, and delayed development are common in very young children with brain tumors. Recent-onset head tilt can result from a posterior fossa tumor.

Brain tumors are the most common solid tumors of childhood, accounting for 1500–2000 new malignancies in
children each year in the United States and for 25%–30% of all childhood cancers. In general, children with brain tumors have a better prognosis than do adults. Favorable outcome occurs most commonly with low-grade and fully resectable tumors. Unfortunately, cranial irradiation in young children can have significant neuropsychological, intellectual, and endocrinologic sequelae.

Brain tumors in childhood are biologically and histologically heterogeneous, ranging from low-grade localized lesions to high-grade tumors with neuraxis dissemination. High-dose systemic chemotherapy is used frequently, especially in young children with high-grade tumors, in an effort to delay, decrease, or completely avoid cranial irradiation. Such intensive treatment may be accompanied by autologous HSCT or peripheral stem cell reconstitution.

The causes of most pediatric brain tumors are unknown. The risk of developing astrocytomas is increased in children with neurofibromatosis or tuberous sclerosis. Several studies show that some childhood brain tumors occur in families with increased genetic susceptibility to childhood cancers in general, brain tumors, or leukemia and lymphoma. A higher incidence of seizures has been observed in relatives of children with astrocytoma. The risk of developing a brain tumor is increased in children who received cranial irradiation for treatment of meningeal leukemia. All children with gliomas and meningiomas should be screened for NF-1. In children with meningiomas, without the skin findings of NF-1, neurofibromatosis type 2 and Von Hippel-Lindau syndrome should be considered. Inherited germline mutations are possible in atypical teratoid/rhabdoid tumors (AT/RTs) and in choroid plexus carcinomas. Careful family histories should be taken in these tumors and genetic counseling considered.

Because pediatric brain tumors are rare, they are often misdiagnosed or diagnosed late; most pediatricians see no more than two children with brain tumors during their careers.

**Clinical Findings**

**A. Symptoms and Signs**

Clinical findings at presentation vary depending on the child’s age and the tumor’s location. Children younger than age 2 years more commonly have infratentorial tumors. Children with such tumors usually present with nonspecific symptoms such as vomiting, unsteadiness, lethargy, and irritability. Signs may be surprisingly few or may include macrocephaly, ataxia, hyperreflexia, and cranial nerve palsies. Because the head can expand in young children, papilledema is often absent. Measuring head circumference and observing gait are essential in evaluating a child for possible brain tumor. Eye findings and apparent visual disturbances such as difficulty tracking can occur in association with optic pathway tumors such as optic glioma. Optic glioma occurring in a young child is often associated with neurofibromatosis.

Older children more commonly have supratentorial tumors, which are associated with headache, visual symptoms, seizures, and focal neurologic deficits. Initial presenting features are often nonspecific. School failure and personality changes are common. Vaguely described visual disturbance is often present, but the child must be directly asked. Headaches are common, but they often will not be predominantly in the morning. The headaches may be confused with migraine.

Older children with infratentorial tumors characteristically present with symptoms and signs of hydrocephalus, which include progressively worsening morning headache and vomiting, gait unsteadiness, double vision, and papilledema. Cerebellar astrocytomas enlarge slowly, and symptoms may worsen over several months. Morning vomiting may be the only symptom of posterior fossa ependymomas, which originate in the floor of the fourth ventricle near the vomiting center. Children with brainstem tumors may present with facial and extraocular muscle palsies, ataxia, and hemiparesis; hydrocephalus occurs in approximately 25% of these patients at diagnosis.

**B. Imaging and Staging**

In addition to the tumor biopsy, neuraxis imaging studies are obtained to determine whether dissemination has occurred. It is unusual for brain tumors in children and adolescents to disseminate outside the CNS.

Magnetic resonance imaging (MRI) has become the preferred diagnostic study for pediatric brain tumors. MRI provides better definition of the tumor and delineates indolent gliomas that may not be seen on computed tomography (CT) scan. In contrast, a CT scan can be done in less than 10 minutes—as opposed to the 30 minutes required for an MRI scan—and is still useful if an urgent diagnostic study is necessary or to detect calcification of a tumor. Both scans are generally done with and without contrast enhancement. Contrast enhances regions where the blood-brain barrier is disrupted. Postoperative scans to document the extent of tumor resection should be obtained within 48 hours after surgery to avoid postsurgical enhancement.

Imaging of the entire neuraxis and CSF cytologic examination should be part of the diagnostic evaluation for patients with tumors such as medulloblastoma, ependymoma, and pineal region tumors. Diagnosis of neuraxis drop metastases (tumor spread along the neuraxis) can be accomplished by gadolinium-enhanced MRI incorporating sagittal and axial views. MRI of the spine should be obtained preoperatively in all children with midline tumors of the fourth ventricle or cerebellum. A CSF sample should be obtained during the diagnostic surgery or, if that is not possible, 7 to 10 days after the surgery. Lumbar CSF is preferred.
over ventricular CSF for cytologic examination. Levels of biomarkers in the blood and CSF, such as human chorionic gonadotropin and \( \alpha \)-fetoprotein, may be helpful at diagnosis and in follow-up. Both human chorionic gonadotropin and \( \alpha \)-fetoprotein should be obtained from the blood preoperatively for all pineal and suprasellar tumors.

The neurosurgeon should discuss staging and sample collection with an oncologist before surgery in a child newly presenting with a scan suggestive of brain tumor.

### C. Classification

About 50% of the common pediatric brain tumors occur above the tentorium and 50% in the posterior fossa. In the very young child, posterior fossa tumors are more common. Most childhood brain tumors can be divided into two categories according to the cell of origin: (1) glial tumors, such as astrocytomas and ependymomas, or (2) nonglial tumors, such as medulloblastoma and other primitive neuroectodermal tumors. Some tumors contain both glial and neural elements (eg, ganglioglioma). A group of less common CNS tumors does not fit into either category (ie, craniopharyngiomas, AT/RTs, germ cell tumors, choroid plexus tumors, and meningiomas). Low- and high-grade tumors are found in most categories. Table 31–3 lists the locations and frequencies of the common pediatric brain tumors.

Astrocytoma is the most common brain tumor of childhood. Most are juvenile pilocytic astrocytoma (WHO grade I) found in the posterior fossa with a bland cellular morphology and few or no mitotic figures. Low-grade astrocytomas are in many cases curable by complete surgical excision alone.

Chemotherapy may be effective in about 40%–50% of low-grade astrocytomas and even in those who will fail chemotherapy eventually, it may delay time to radiation.

Medulloblastoma and related primitive neuroectodermal tumors are the most common high-grade brain tumors in children. These tumors usually occur in the first decade of life, with a peak incidence between ages 5 and 10 years and a female-male ratio of 2.1:1.3. The tumors typically arise in the midline cerebellar vermis, with variable extension into the fourth ventricle. Neuraxis dissemination at diagnosis affects from 10% to 46% of patients. Prognostic factors are outlined in Table 31–4. Determination of risk using histology may soon be replaced by molecular classifications.

Brainstem tumors are third in frequency of occurrence in children. They are frequently of astrocytic origin and often are high grade. Children with tumors that diffusely infiltrate the brainstem and involve primarily the pons (diffuse intrinsic pontine gliomas) have a long-term survival rate of less than 5%. There has been considerable biological discovery, largely from autopsy samples, in diffuse pontine gliomas in the very recent past; it is hoped this will result in new, better targeted therapies. Brainstem tumors that occur above or below the pons and grow in an eccentric or cystic manner have a somewhat better outcome. Exophytic tumors in this location may be amenable to surgery. Generally, brainstem tumors are treated without a tissue diagnosis.

Other brain tumors such as ependymomas, germ cell tumors, choroid plexus tumors, and craniopharyngiomas are less common, and each is associated with unique diagnostic and therapeutic challenges.

### Treatment

#### A. Supportive Care

Dexamethasone should be started prior to initial surgery (0.5–1.0 mg/kg initially, then 0.25–0.5 mg/kg/d in four divided doses). Anticonvulsants should be started if the child has had a seizure or if the surgical approach is likely to induce seizures. Keppra is now the preferred anticonvulsant in this population as it does not induce liver enzymes. Because postoperative treatment of young children with high-grade brain tumors incorporates increasingly more
intensive systemic chemotherapy, consideration should also be given to the use of prophylaxis for prevention of oral candidiasis and Pneumocystis infection. Dexamethasone potentially reduces the effectiveness of chemotherapy and should be discontinued as soon after surgery as possible.

Optimum care for the pediatric patient with a brain tumor requires a multidisciplinary team including subspecialists in pediatric neurosurgery, neuro-oncology, neurology, endocrinology, neuropsychology, radiation therapy, and rehabilitation medicine, as well as highly specialized nurses, social workers, and staff in physical therapy, occupational therapy, and speech and language science.

**B. Specific Therapy**

The goal of treatment is to eradicate the tumor with the least short- and long-term morbidity. Long-term neuropsychological morbidity becomes an especially important issue related to deficits caused by the tumor itself and the sequelae of treatment. Meticulous surgical removal of as much tumor as possible is generally the preferred initial approach. Technologic advances in the operating microscope, the ultrasonic tissue aspirator, and the CO\(_2\) laser (which is less commonly used in pediatric brain tumor surgery); the accuracy of computerized stereotactic resection; and the availability of intraoperative monitoring techniques such as evoked potentials and electrocorticography have increased the feasibility and safety of surgical resection of many pediatric brain tumors. Second-look surgery after chemotherapy is increasingly being used when tumors are incompletely resected at initial surgery.

Radiation therapy for pediatric brain tumors is in a state of evolution. For tumors with a high probability of neuraxis dissemination (eg, medulloblastoma), craniospinal irradiation is still standard therapy in children older than age 3 years. For tumors, such as medulloblastomas, there are ongoing trials aimed at further reducing the craniospinal dose. In others (eg, ependymomas), craniospinal irradiation has been abandoned because neuraxis dissemination at first relapse is rare. Conformal radiation and the use of three-dimensional treatment planning are now in routine.

Chemotherapy is effective in treating low-grade and malignant astrocytomas and medulloblastomas. There is an initial report supporting the effectiveness of chemotherapy in AT/RTs. The therapy used in this study was prolonged and intensive. The utility of chemotherapy in ependymoma is being re-explored in national trials. A series of brain tumor protocols for children younger than age 3 years involved administering intensive chemotherapy after tumor resection and delaying or omitting radiation therapy. The results of these trials have generally been disappointing but have taught valuable lessons regarding the varying responses to chemotherapy of different tumor types. Superior results seem to have been obtained in the very young with high-dose chemotherapy strategies with stem cell rescue often followed by conformal radiotherapy. Conformal techniques allow the delivery of radiation to strictly defined fields and may limit side effects.

Perhaps the most exciting development in pediatric neuro-oncology is the development of biologically and clinically relevant subclassifications in both medulloblastoma and ependymoma. This development will drive a new generation of targeted therapy aimed at these biologically defined groups. The consensus definition of four biologically defined entities in medulloblastoma, including the Wnt and SHH groups, is the best example of this. New studies are in the planning stage based on this new defined biology.

In older children with malignant glioma, the current approach is surgical resection of the tumor and combined-modality treatment with irradiation and intensive chemotherapy. It has recently been realized there is considerable heterogeneity in pediatric high-grade gliomas. Some, such as the congenital tumors, may do well with relatively modest therapy. Others, such as epithelioid glioblastomas may harbor Braf mutations and may be targetable with specific agents. Generally, however, the prognosis is poor for children with high-grade gliomas and there has been little progress in finding better chemotherapeutic agents and strategies for most children with these devastating tumors.

The treatment of low-grade astrocytomas, which cannot be completely excised, has likewise shown only disappointing progress. The chemotherapy agents currently in use have high failure rates and some children suffer multiple, neurologically damaging, relapses. Radiotherapy with its improved conformational techniques is perhaps being delayed too long in some children.

**Prognosis**

Despite improvements in surgery and radiation therapy, the outlook for cure remains poor for children with high-grade glial tumors. For children with high-grade gliomas, an early CCG study showed a 45% progression-free survival rate for children who received radiation therapy and chemotherapy, but this may have been due to the inclusion of low-grade patients. More recent studies would suggest survival rate of less than 10%. The major exception to this is congenital glioblastomas which appear to have a much more favorable prognosis. Biologic factors that may affect survival are being increasingly recognized. The prognosis for diffuse pontine gliomas remains very poor, with the standard therapy of radiation alone, being only palliative.

The 5- and even 10-year survival rate for low-grade astrocytomas of childhood is 60%–90%. However, prognosis depends on both site, grade and, it is increasingly realized, on biology. A child with a pilocytic astrocytoma of the cerebellum has a considerably better prognosis than a child with a fibrillary astrocytoma of the cerebral cortex. Pilomyxoid astrocytomas
have been recently designated a grade II tumor and have a worse prognosis. For recurrent or progressive low-grade astrocytoma of childhood, relatively moderate chemotherapy may improve the likelihood of survival.

Conventional craniospinal irradiation for children with low-stage medulloblastoma results in survival rates of 60%–90%. Ten-year survival rates are lower (40%–60%). Chemotherapy allows a reduction in the craniospinal radiation dose while improving survival rates for average-risk patients (86% survival at 5 years on the most recent COG average-risk protocol). However, even reduced-dose craniospinal irradiation has an adverse effect on intellect, especially in children younger than age 7 years. Five-year survival rates for high-risk medulloblastoma have been 25%–40%, but this may be improved with the introduction of more chemotherapy during radiation although this still awaits the results of formal trials.

The previously poor prognosis for children with AT/RT’s seems improved by intensive multimodality therapy. A single center study suggests an improved outcome for ependymoma using conformational radiation techniques. This awaits confirmation by a national study.

Major challenges remain in treating brain tumors in children younger than age 3 years and in treating brainstem gliomas and malignant gliomas. The increasing emphasis is on the quality of life of survivors, not just the survival rate.

In contrast, the term leukemia refers to a malignancy arising from the bone marrow, which may include lymphoid cells. Because lymphomas can involve the bone marrow, the distinction between the two can be confusing. The diagnosis of lymphoma is a common one among childhood cancers, accounting for 10%–15% of all malignancies. The most common form is Hodgkin disease, which represents nearly half of all cases. The remaining subtypes, referred to collectively as non-Hodgkin lymphoma, are divided into four main groups: lymphoblastic, small noncleaved cell, large B-cell, and anaplastic large cell lymphomas.

In contrast to lymphomas, lymphoproliferative disorders (LPDs) are quite rare in the general population. Most are polyclonal, nonmalignant (though often life-threatening) accumulations of lymphocytes that occur when the immune system fails to control virally transformed lymphocytes. However, a malignant monoclonal proliferation can also arise. The posttransplant LPDs arise in patients who are immunosuppressed to prevent solid organ or bone marrow transplant rejection, particularly liver and heart transplant patients. Spontaneous LPDs occur in immunodeficient individuals and, less commonly, in immunocompetent persons.

### 1. Hodgkin Lymphoma

#### General Considerations

Children with Hodgkin lymphoma have a better response to treatment than do adults, with a 75% overall survival rate at more than 20 years following diagnosis. Although adult therapies are applicable, the management of Hodgkin lymphoma in children younger than age 18 years frequently differs. Because excellent disease control can result from several different therapeutic approaches, selection of staging procedures (radiographic, surgical, or other procedures to determine additional locations of disease) and treatment are often based on the potential long-term toxicity associated with the intervention.

Although Hodgkin lymphoma represents 50% of the lymphomas of childhood, only 15% of all cases occur in children aged 16 years or younger. Children younger than age 5 years account for 3% of childhood cases. There is a 4:1 male predominance in the first decade. Notably, in underdeveloped countries, the age distribution is quite different, with a peak incidence in younger children.

Hodgkin disease is subdivided into four histologic groups, and the distribution in children parallels that of adults: lymphocyte-predominant (10%–20%); nodular sclerosing (40%–60%); mixed cellularity (20%–40%); and lymphocyte-depleted (5%–10%). Prognosis is independent of sub-classification, with appropriate therapy based on stage (see section on “Staging”).

#### LYMPHOMAS & LYMPHOPROLIFERATIVE DISORDERS

The term lymphoma refers to a malignant proliferation of lymphoid cells, usually in association with and arising from lymphoid tissues (ie, lymph nodes, thymus, spleen).
Clinical Findings

A. Symptoms and Signs

Children with Hodgkin lymphoma usually present with painless cervical adenopathy. The lymph nodes often feel firmer than inflammatory nodes and have a rubbery texture. They may be discrete or matted together and are not fixed to surrounding tissue. The growth rate is variable, and involved nodes may wax and wane in size over weeks to months.

As Hodgkin lymphoma nearly always arises in lymph nodes and spreads to contiguous nodal groups, a detailed examination of all nodal sites is mandatory. Lymphadenopathy is common in children, so the decision to perform biopsy is often difficult or delayed for a prolonged period. Indications for consideration of early lymph node biopsy include lack of identifiable infection in the region drained by the enlarged node, a node greater than 2 cm in size, supraclavicular adenopathy or abnormal chest radiograph, and lymphadenopathy increasing in size after 2 weeks or failing to resolve within 4–8 weeks.

 Constitutional symptoms occur in about one-third of children at presentation. Symptoms of fever greater than 38.0°C, weight loss of 10% in the previous 6 months, and drenching night sweats are defined by the Ann Arbor staging criteria as B symptoms. The A designation refers to the absence of these symptoms. B symptoms are of prognostic value, and more aggressive therapy is usually required for cure. Generalized pruritus and pain with alcohol ingestion may also occur.

Half of patients have asymptomatic mediastinal disease (adenopathy or anterior mediastinal mass), although symptoms due to compression of vital structures in the thorax may occur. A chest radiograph should be obtained when lymphoma is being considered. The mediastinum must be evaluated thoroughly before any surgical procedure is undertaken to avoid airway obstruction or cardiovascular collapse during anesthesia and possible death. Splenomegaly or hepato- megaly is generally associated with advanced disease.

B. Laboratory Findings

The CBC is usually normal, although anemia, neutrophilia, eosinophilia, and thrombocytosis may be present. The erythrocyte sedimentation rate and other acute-phase reactants are often elevated and can serve as markers of disease activity. Immunologic abnormalities occur, particularly in cell-mediated immunity, and anergy is common in patients with advanced-stage disease at diagnosis. Autoantibody phenomena such as hemolytic anemia and an idiopathic thrombocytopenic purpura–like picture have been reported.

C. Staging

Staging of Hodgkin lymphoma determines treatment and prognosis. The most common staging system is the Ann Arbor classification that describes extent of disease by I–IV and symptoms by an A or a B suffix (eg, stage IIIIB). A systematic search for disease includes chest radiography; CT scan of the chest, abdomen, and pelvis; and bilateral bone marrow aspirates and biopsies. Technetium bone scanning may show bony involvement and is usually reserved for patients with bone pain, as bone involvement is rare. In recent years, positron emission tomography is increasingly used in the staging and follow-up of patients with Hodgkin disease, often replacing gallium scanning.

The staging laparotomy in pediatrics is rarely performed because almost all patients are given systemic chemotherapy rather than radiation therapy. This shift in favored therapy is due to the toxicities of high-dose, extended-field radiation in children and the complications of laparotomy, including postsplenectomy sepsis.

D. Pathologic Findings

The diagnosis of Hodgkin lymphoma requires the histologic presence of the Reed-Sternberg cell or its variants in tissue. Reed-Sternberg cells are germinal-center B cells that have undergone malignant transformation. Nearly 20% of these tumors in developed countries are positive for EBV. EBV has been linked to Hodgkin disease and the large portion of Hodgkin patients with increased EBV titers suggests that EBV activation may contribute to the onset of Hodgkin lymphoma.

Treatment & Prognosis

Treatment decisions are based on presence of B symptoms, stage, tumor bulk, and number of involved nodal regions. To achieve long-term disease-free survival while minimizing treatment toxicity, Hodgkin disease is increasingly treated by chemotherapy alone—and less often by radiation therapy. Several combinations of chemotherapeutic agents are effective, and treatment times are relatively short compared with pediatric oncology protocols for leukemia. A recently completed COG study addressed whether only 9 weeks of therapy with AV-PC (Adriamycin [doxorubicin], vincristine, prednisone, and cyclophosphamide) is sufficient to induce a complete response in patients with low-risk Hodgkin lymphoma. Two additional drugs, bleomycin and etoposide, are currently added in the treatment of intermediate-risk patients for a total of 4–6 months of therapy for patients with intermediate-risk disease. The removal of involved field irradiation in patients with intermediate-risk Hodgkin lymphoma who respond early to chemotherapy is being investigated. Combined-modality therapy with chemotherapy and irradiation is used in advanced disease.

Current treatment gives children with stage I and stage II Hodgkin lymphoma at least a 90% disease-free likelihood of survival 5 years after diagnosis, which generally equates with cure. Two-thirds of all relapses occur within 2 years after...
diagnosis, and relapse rarely occurs beyond 4 years. In more advanced disease (stages III and IV), 5-year event-free survival rates range from over 60% to 90%. With more patients being long-term survivors of Hodgkin disease, the risk of secondary malignancies, both leukemias and solid tumors, is becoming more apparent and is higher in patients receiving radiation therapy. Therefore, elucidating the optimal treatment strategy that minimizes such risk should be the goal of future studies.

Patients with relapsed Hodgkin lymphoma are often salvageable using chemotherapy and radiation therapy. An increasingly popular alternative is autologous HSCT, which may improve survival rates. Allogeneic HSCT is also used, but carries increased risks of complications and may not offer added survival benefit.

Targeted therapies are being tested for children with high-risk Hodgkin lymphoma, including antibody conjugates targeting CD30, a transmembrane receptor highly expressed in Hodgkin lymphoma. Other agents being considered in the high-risk group are histone deacetylase inhibitors and mTOR inhibitors.

2. Non-Hodgkin Lymphoma

General Considerations

Non-Hodgkin lymphomas (NHLs) are a diverse group of cancers accounting for 5%–10% of malignancies in children younger than age 15 years. About 500 new cases arise per year in the United States. The incidence of NHLs increases with age. Children aged 15 years or younger account for only 3% of all cases of NHLs, and the disease is uncommon before age 5 years. There is a male predominance of approximately 3:1. In equatorial Africa, NHLs cause almost 50% of pediatric malignancies.

Most children who develop NHL are immunologically normal. However, children with congenital or acquired immune deficiencies (eg, Wiskott-Aldrich syndrome, severe combined immunodeficiency syndrome, X-linked lymphoproliferative syndrome, HIV infection, immunosuppressive therapy following solid organ or marrow transplantation) have an increased risk of developing NHLs. It has been estimated that their risk is 100–10,000 times that of age-matched control subjects.

Animal models suggest a viral contribution to the pathogenesis of NHL, and there is evidence of viral involvement in human NHL as well. In equatorial Africa, 95% of Burkitt lymphomas contain DNA from the EBV. But in North America, less than 20% of Burkitt tumors contain the EBV genome. The role of other viruses (eg, human herpesviruses 6 and 8), disturbances in host immunologic defenses, chronic immunostimulation, and specific chromosomal rearrangements as potential triggers in the development of NHL is under investigation.

Unlike adult NHL, virtually all childhood NHLs are rapidly proliferating, high-grade, diffuse malignancies. These tumors exhibit aggressive behavior but are usually very responsive to treatment. Nearly all pediatric NHLs are histologically classified into four main groups: lymphoblastic lymphoma (LL), small noncleaved cell lymphoma (Burkitt lymphoma [BL] and Burkitt-like lymphoma [BLL]), large B-cell lymphoma (LBCL), and anaplastic large cell lymphoma (ALCL). Immunophenotyping and cytogenetic features, in addition to clinical presentation, are increasingly important in the classification, pathogenesis, and treatment of NHLs. Comparisons of pediatric NHLs are summarized in Table 31–5.

Clinical Findings

A. Symptoms and Signs

Childhood NHLs can arise in any site of lymphoid tissue, including lymph nodes, thymus, liver, and spleen. Common extralymphatic sites include bone, bone marrow, CNS, skin, and testes. Signs and symptoms at presentation are determined by the location of lesions and the degree of dissemination. Because NHL usually progresses very rapidly, the duration of symptoms is quite brief, from days to a few weeks. Nevertheless, children present with a limited number of syndromes, most of which correlate with cell type.

Children with LL often present with symptoms of airway compression (cough, dyspnea, orthopnea) or superior vena cava obstruction (facial edema, chemosis, plethora, venous engorgement), which are a result of mediastinal disease. These symptoms are a true emergency necessitating rapid diagnosis and treatment. Pleural or pericardial effusions may further compromise the patient’s respiratory and cardiovascular status. CNS and bone marrow involvement are not common at diagnosis. When bone marrow contains more than 25% lymphoblasts, patients are diagnosed with ALL.

Most patients with BL and BLL present with abdominal disease. Abdominal pain, distention, a right lower quadrant mass, or intussusception in a child older than age 5 years suggests the diagnosis of BL. Bone marrow involvement is common (~65% of patients). BL is the most rapidly proliferating tumor known and has a high rate of spontaneous cell
death as it outgrows its blood supply. Consequently, children presenting with massive abdominal disease frequently have tumor lysis syndrome (hyperuricemia, hyperphosphatemia, and hyperkalemia). These abnormalities can be aggravated by tumor infiltration of the kidney or urinary obstruction by tumor. Although similar histologically, numerous differences exist between cases of BL occurring in endemic areas of equatorial Africa and the sporadic cases of North America (Table 31–6).

Large cell lymphomas are similar clinically to the small noncleaved cell lymphomas, although unusual sites of involvement are quite common, particularly with ALCL. Skin lesions, focal neurologic deficits, and pleural or peritoneal effusions without an obvious associated mass are frequently seen.

### B. Diagnostic Evaluation

Diagnosis is made by biopsy of involved tissue with histology, immunophenotyping, and cytogenetic studies. If mediastinal disease is present, general anesthesia must be avoided if the airway or vena cava is compromised by tumor. In these cases samples of pleural or ascitic fluid, bone marrow, or peripheral nodes obtained under local anesthesia (in the presence of an anesthesiologist) may confirm the diagnosis. Major abdominal surgery and intestinal resection should be avoided in patients with an abdominal mass that is likely to be BL, as the tumor will regress rapidly with the initiation of chemotherapy. The rapid growth of these tumors and

CNS, central nervous system; EBV, Epstein-Barr virus.
the associated life-threatening complications demand that further studies be done expeditiously so that specific therapy is not delayed.

After a thorough physical examination, a CBC, liver function tests, and a biochemical profile (electrolytes, calcium, phosphorus, uric acid, renal function) should be obtained. An elevated LDH reflects tumor burden and can serve as a marker of disease activity. Imaging studies should include a chest radiograph and chest CT scan, an abdominal ultrasound or CT scan, and possibly a positron emission tomography scan. Bone marrow and CSF examinations are also essential.

**Treatment**

**A. Supportive Care**

The management of life-threatening problems at presentation is critical. The most common complications are superior mediastinal syndrome and acute tumor lysis syndrome. Patients with airway compromise require prompt initiation of specific therapy. Because of the risk of general anesthesia in these patients, it is occasionally necessary to initiate corticosteroids or low-dose emergency radiation therapy until the mass is small enough for a biopsy to be undertaken safely. Response to steroids and radiation therapy is usually prompt (12–24 hours).

Tumor lysis syndrome should be anticipated in all patients who have NHL with a large tumor burden. Maintaining a brisk urine output (> 5 mL/kg/h) with intravenous fluids and diuretics is the key to management. Allopurinol will reduce serum uric acid, and alkalization of urine will increase its solubility. Rasburicase is an effective intravenous alternative to allopurinol and is increasingly used for patients with high risk of tumor lysis based on tumor burden or in patients who do not have an optimal response to allopurinol. Because phosphate precipitates in alkaline urine, alkali administration should be discontinued if hyperphosphatemia occurs. Renal dialysis is occasionally necessary to control metabolic abnormalities. Every attempt should be made to correct or minimize metabolic abnormalities before initiating chemotherapy; however, this period of stabilization should not exceed 24–48 hours.

**B. Specific Therapy**

Systemic chemotherapy is the mainstay of therapy for NHLs. Nearly all patients with NHL require intensive intrathecal chemotherapy for CNS prophylaxis. Surgical resection is not indicated unless the entire tumor can be resected safely, which is rare. Partial resection or debulking surgery has no role. Radiation therapy does not improve outcome, so its use is confined to exceptional circumstances.

Therapy for LL is generally based on treatment protocols designed for ALL and involves dose-intensive, multiagent chemotherapy. The duration of therapy is 2 years. Treatment of BL and BLL using alkylating agents and intermediate- to high-dose methotrexate administered intensively but for a relatively short time produce the highest cure rates. LBCL is treated similarly, whereas ALCL has been treated with both BL and LL protocols.

Monoclonal antibodies such as rituximab (anti-CD20) allow for more targeted therapy of lymphomas and have been successful in improving outcomes in adults. Studies employing this type of therapy in children are underway in those with newly diagnosed as well as relapsed or refractory B-cell NHL. Additionally, inhibitors against the ALK oncogene are being explored as novel therapy for specific subsets of patients with NHL. Specifically, the ALK oncogene (activated by a 2:5 translocation leading to juxtaposition of NPM N-terminal region to the intracellular part of ALK) is the defining genetic lesions in ALK-positive ALCL and in rare variants of LBCL. Molecular profiling of pediatric lymphomas has identified other potential biologic targets. Developing therapeutics against biologic targets may improve outcomes for patients, particularly those patients with advanced stage disease, while reducing the potential for late effects.

**Prognosis**

A major predictor of outcome in NHL is the extent of disease at diagnosis. Ninety percent of patients with localized disease can expect long-term, disease-free survival. Patients with extensive disease on both sides of the diaphragm, CNS involvement, or bone marrow involvement in addition to a primary site have a 70%-80% failure-free survival rate. Relapses occur early in NHL; patients with LL rarely have recurrences after 30 months from diagnosis, whereas patients with BL and BLL very rarely have recurrences beyond 1 year. Patients who experience relapse may have a chance for cure by autologous or allogeneic HSCT.

---

3. Lymphoproliferative Disorders

LPDs can be thought of as a part of a continuum with lymphomas. Whereas LPDs represent inappropriate, often polyclonal proliferations of nonmalignant lymphocytes, lymphomas represent the development of malignant clones, sometimes arising from recognized LPDs.

A. Posttransplantation Lymphoproliferative Disorders

Posttransplantation lymphoproliferative disorders (PTLDs) arise in patients who have received substantial immunosuppressive medications for solid organ or bone marrow transplantation. In these patients, reactivation of latent EBV infection in B cells drives a polyclonal proliferation of these cells that is fatal if not halted. Occasionally a true lymphoma develops, often bearing a chromosomal translocation.

LPDs are an increasingly common and significant complication of transplantation. The incidence of PTLD ranges from approximately 2% to 15% of transplant recipients, depending on the organ transplanted and the immunosuppressive regimen.

Treatment of these disorders is a challenge for transplant physicians and oncologists. The initial treatment is reduction in immunosuppression, which allows the patient’s own immune cells to destroy the virally transformed lymphocytes. However, this is only effective in approximately half of the patients. For those patients who do not respond to reduced immune suppression, chemotherapy of various regimens may succeed. The use of anti-B-cell antibodies, such as rituximab (anti-CD20), for the treatment of PTLDs has been promising in clinical trials. More recently, T-cell-based immune therapies, such as donor lymphocyte infusions and adoptive transfer of EBV-specific cytotoxic T lymphocytes have also been explored as novel approaches.

B. Spontaneous Lymphoproliferative Disease

Immunodeficiencies in which LPDs occur include Bloom syndrome, Chédiak-Higashi syndrome, ataxia-telangiectasia, Wiskott-Aldrich syndrome, X-linked lymphoproliferative syndrome, congenital T-cell immunodeficiencies, and HIV infection. Treatment depends on the circumstances, but unlike PTLD, few therapeutic options are often available.

Castleman disease is an LPD occurring in pediatric patients without any apparent immunodeficiency. The autoimmune lymphoproliferative syndrome (ALPS) is characterized by widespread lymphadenopathy with hepatosplenomegaly, and autoimmune phenomena. ALPS results from mutations in the Fas ligand pathway that is critical in regulation of apoptosis.

NEUROBLASTOMA

General Considerations

Neuroblastoma arises from neural crest tissue of the sympathetic ganglia or adrenal medulla. It is composed of small, fairly uniform cells with little cytoplasm and hyperchromatic nuclei that may form rosette patterns. Pathologic diagnosis is not always easy, and neuroblastoma must be differentiated from the other “small, round, blue cell” malignancies of childhood (Ewing sarcoma, rhabdomyosarcoma, peripheral neuroectodermal tumor, and lymphoma).

Neuroblastoma accounts for 7%–10% of pediatric malignancies and is the most common solid neoplasm outside the CNS. Fifty percent of neuroblastomas are diagnosed before age 2 years and 90% before age 5 years.

Neuroblastoma is a biologically diverse disease with varied clinical behavior ranging from spontaneous regression to progression through very aggressive therapy. Unfortunately, despite significant advances in our understanding of this tumor at the cellular and molecular level, the overall survival rate in advanced disease has changed little in 20 years, with 3-year event-free survival being less than 15%.

Clinical Findings

A. Symptoms and Signs

Clinical manifestations vary with the primary site of malignant disease and the neuroendocrine function of the tumor. Many children present with constitutional symptoms such as fever, weight loss, and irritability. Bone pain suggests metastatic disease, which is present in 60% of children older than 1 year of age at diagnosis. Physical examination may reveal a firm, fixed, irregularly shaped mass that extends beyond the midline. The margins are often poorly defined. Although most children have an abdominal primary tumor (40% adrenal gland, 25% paraspinal ganglion), neuroblastoma can arise wherever there is sympathetic tissue. In the posterior mediastinum, the tumor is usually asymptomatic and discovered on a chest radiograph obtained for other reasons. Patients with cervical neuroblastoma present with a neck mass, which is often misdiagnosed as infection. Horner syndrome (unilateral ptosis, myosis, and anhidrosis) or heterochromia iridis (differently colored irises) may accompany...
cervical neuroblastoma. Paraspinal tumors can extend through the spinal foramina, causing cord compression. Patients may present with paresis, paralysis, and bowel or bladder dysfunction.

The most common sites of metastases are bone, bone marrow, lymph nodes (regional as well as disseminated), liver, and subcutaneous tissue. Neuroblastoma has a predilection for metastasis to the skull, in particular the sphenoid bone and retrobulbar tissue. This causes periorbital ecchymosis and proptosis. Liver metastasis, particularly in the newborn, can be massive. Subcutaneous nodules are bluish in color and associated with an erythematous flush followed by blanching when compressed, probably secondary to catecholamine release.

Neuroblastoma may also be associated with unusual paraneoplastic manifestations. Perhaps the most striking example is opsoclonus-myoclonus, also called dancing eyes/dancing feet syndrome. This phenomenon is characterized by the acute onset of rapid and chaotic eye movements, myoclonic jerking of the limbs and trunk, ataxia, and behavioral disturbances. This process, which often persists after therapy is complete, is thought to be secondary to cross-reacting anti-neural antibodies. Intractable, chronic watery diarrhea is associated with tumor secretion of vasoactive intestinal peptides. Both of these paraneoplastic syndromes are associated with favorable outcomes.

B. Laboratory Findings

Anemia is present in 60% of children with neuroblastoma and can be due to chronic disease or marrow infiltration. Occasionally, thrombocytopenia is present, but thrombocytosis is a more common finding, even with metastatic disease in the marrow. Urinary catecholamines (vanillylmandelic acid and homovanillic acid) are elevated in at least 90% of patients at diagnosis and should be measured prior to surgery.

C. Imaging

Plain radiographs of the primary tumor may show stippled calcifications. Metastases to bone appear irregular and lytic. Periosteal reaction and pathologic fractures may also be seen. CT scanning provides more information, including the extent of the primary tumor, its effects on surrounding structures, and the presence of liver and lymph node metastases. Classically, in tumors originating from the adrenal gland, the kidney is displaced inferolaterally, which helps to differentiate neuroblastoma from Wilms tumor. MRI is useful in determining the presence of spinal cord involvement in tumors that appear to invade neural foramina.

Technetium bone scanning is obtained for the evaluation of bone metastases, because the tumor usually takes up technetium. Metaiodobenzylguanidine (MIBG) scanning is also performed to detect metastatic disease.

D. Staging

Staging of neuroblastoma is performed according to the International Neuroblastoma Staging System (INSS) (Table 31–7). A biopsy of the tumor is performed to determine the biologic characteristics of the tumor. In addition, bilateral bone marrow aspirates and biopsies must be performed to evaluate marrow involvement.

Tumors are classified as favorable or unfavorable based on histologic characteristics. Amplification of the MYCN protooncogene is a reliable marker of aggressive clinical behavior with rapid disease progression. Tumor cell DNA content is also predictive of outcome. Hyperdiploidy is a favorable finding, whereas diploid DNA content is associated with a worse outcome.

Treatment & Prognosis

Patients are treated based on a risk stratification system adopted by the COG based on INSS stage, age, MYCN status, histology, cytogenetic findings, and DNA index. The mainstay of therapy is surgical resection coupled with chemotherapy.

</tr>
</tbody>
</table>
The usually massive size of the tumor often makes primary resection impossible. Under these circumstances, only a biopsy is performed. Following chemotherapy, a second surgical procedure may allow for resection of the primary tumor. Radiation therapy is sometimes also necessary. Effective chemotherapeutic agents in the treatment of neuroblastoma include cyclophosphamide, doxorubicin, etoposide, cisplatin, vincristine, and topotecan. About 80% of patients achieve complete or partial remission, although in advanced disease, remission is seldom durable.

For low-risk disease (stage 1 and 2, with good biologic features), surgical resection alone may be sufficient to affect a cure. Infants younger than 1 year with stage 4S disease may need little if any therapy, although chemotherapy may be initiated because of bulky disease causing mechanical complications. In intermediate-risk neuroblastoma (subsets of patients with stage 3 and 4 disease), the primary treatment approach is surgical combined with chemotherapy. High-risk patients (the majority with stage 3 and 4 disease) require multimodal therapy, including surgery, irradiation, chemotherapy, and autologous HSCT. The administration of cis-retinoic acid, a differentiating agent, can prolong disease-free survival in advanced-stage neuroblastoma when administered in the setting of minimal residual disease (MRD) after HSCT.

A recent cooperative clinical trial concluded that administration of ch14.18 (a monoclonal antibody specific for the predominant antigen on neuroblastoma cells) and cytokines improves outcome in the high-risk population following HSCT. All patients with high-risk disease are offered this therapy. The current COG trial for high-risk patients is comparing single versus tandem HSCT in this population. Fenretinide, a synthetic retinoid, and radiolabeled MIBG are also under investigation.

For children with stage 1, 2, or 4S disease, the 5-year survival rate is 70%–90%. Infants younger than 460 days old have a greater than 80% likelihood of long-term survival. Children older than age 1 year with stage 3 disease have an intermediate prognosis (~40%–70%). Older patients with stage 4 disease have a poor prognosis (5%–50% survival 5 years from diagnosis), although patients 12–18 months old with hyperdiploidy and nonamplified MYCN have an excellent prognosis.

**WILMS TUMOR (NEPHROBLASTOMA)**

**General Considerations**

Approximately 460 new cases of Wilms tumor occur annually in the United States, representing 5%–6% of cancers in children younger than age 15 years. After neuroblastoma, this is the second most common abdominal tumor in children. The majority of Wilms tumors are of sporadic occurrence. However, in a few children, Wilms tumor occurs in the setting of associated malformations or syndromes, including aniridia, hemihypertrophy, genitourinary malformations (eg, cryptorchidism, hypospadias, gonadal dysgenesis, pseudohemaphroditism, and horseshoe kidney), Beck-with-Wiedemann syndrome, Denys-Drash syndrome, and WAGR syndrome (Wilms tumor, aniridia, ambiguous genitalia, mental retardation).

The median age at diagnosis is related both to gender and laterality, with bilateral tumors presenting at a younger age than unilateral tumors, and males being diagnosed earlier than females. Wilms tumor occurs most commonly between ages 2 and 5 years; it is unusual after age 6 years. The mean age at diagnosis is 4 years.

**Clinical Findings**

**A. Symptoms and Signs**

Most children with Wilms tumor present with increasing size of the abdomen or an asymptomatic abdominal mass incidentally discovered by a parent and/or health care provider. The mass is usually smooth and firm, well demarcated, and rarely crosses the midline, though it can extend inferiorly into the pelvis. About 25% of patients are hypertensive at presentation. Gross hematuria is an uncommon presentation, although microscopic hematuria occurs in approximately 25% of patients.

**B. Laboratory Findings**

The CBC is usually normal, but some patients have anemia secondary to hemorrhage into the tumor. Blood urea nitrogen and serum creatinine are usually normal. Urinalysis may show some blood or leukocytes.
C. Imaging and Staging

Ultrasonography or CT of the abdomen should establish the presence of an intrarenal mass. It is also essential to evaluate the contralateral kidney for presence and function as well as synchronous Wilms tumor. The inferior vena cava needs to be evaluated by ultrasonography with Doppler flow for the presence and extent of tumor propagation. The liver should be imaged for the presence of metastatic disease. Chest CT scan should be obtained to determine whether pulmonary metastases are present. Approximately 10% of patients will have metastatic disease at diagnosis. Of these, 80% will have pulmonary disease and 15% liver metastases. Bone and brain metastases are extremely uncommon and usually associated with the rarer, more aggressive renal tumor types, such as clear cell sarcoma or rhabdoid tumor; hence, bone scans and brain imaging are not routinely performed. The clinical stage is ultimately decided at surgery and confirmed by the pathologist.

Treatment & Prognosis

In the United States, treatment of Wilms tumor begins with surgical exploration of the abdomen via an anterior surgical approach to allow for inspection and palpation of the contralateral kidney. The liver and lymph nodes are inspected and suspicious areas biopsied or excised. En bloc resection of the tumor is performed. Every attempt is made to avoid tumor spillage at surgery as this may increase the staging and treatment. Because therapy is tailored to tumor stage, it is imperative that a surgeon familiar with the staging requirements perform the operation.

In addition to the staging, the histologic type has implications for therapy and prognosis. Favorable histology (FH; see later discussion) refers to the classic triphasic Wilms tumor and its variants. Unfavorable histology (UH) refers to the presence of diffuse anaplasia (extreme nuclear atypia) and is present in 5% of Wilms tumors. Only a few small foci of anaplasia in a Wilms tumor give a worse prognosis to patients with stage II, III, or IV tumors. Loss of heterozygosity of chromosomes 1p and 16q are adverse prognostic factors in those with favorable histology. Following excision and pathologic examination, the patient is assigned a stage that defines further therapy.

Improvement in the treatment of Wilms tumor has resulted in an overall cure rate of approximately 90%. The National Wilms Tumor Study Group’s fourth study (NWTS-4) demonstrated that survival rates were improved by intensifying therapy during the initial treatment phase while shortening overall treatment duration (24 weeks vs 60 weeks of treatment).

Table 31–8 provides an overview of the current treatment recommendations in NWTS-5. Patients with stage III or IV Wilms tumor require radiation therapy to the tumor bed and to sites of metastatic disease. Chemotherapy is optimally begun within 5 days after surgery, whereas radiation therapy should be started within 10 days. Stage V (bilateral Wilms tumor) disease dictates a different approach, consisting of possible bilateral renal biopsies followed by chemotherapy and second-look renal-sparing surgery. Radiation therapy may also be necessary.

Using these approaches, 4-year overall survival rates through NWTS-4 are as follows: stage I FH, 96%; stage II–IV FH, 82%–92%; stage I–III UH (diffuse anaplasia), 56%–70%; stage IV UH, 17%. Patients with recurrent Wilms tumor have a salvage rate of approximately 50% with surgery, radiation therapy, and chemotherapy (singly or in combination). HSCT is also being explored as a way to improve the chances of survival after relapse.

Future Considerations

Although progress in the treatment of Wilms tumor has been extraordinary, important questions remain to be answered. Questions have been raised regarding the role of prenephrectomy chemotherapy in the treatment of Wilms tumor. Presurgical chemotherapy seems to decrease tumor rupture at resection but may unfavorably affect outcome by changing staging. Future studies will be directed at minimizing acute and long-term toxicities for those with low-risk disease and improving outcomes for those with high-risk and recurrent disease.
Primary malignant bone tumors are uncommon in childhood with only 650–700 new cases per year. Osteosarcoma accounts for 60% of cases and occurs mostly in adolescents and young adults. Ewing sarcoma is the second most common malignant tumor of bony origin and occurs in toddlers to young adults. Both tumors have a male predominance. The cardinal signs of bone tumor are pain at the site of involvement, often following slight trauma, mass formation, and fracture through an area of cortical bone destruction.

1. Osteosarcoma

General Considerations

Although osteosarcoma is the sixth most common malignancy in childhood, it ranks third among adolescents and young adults. This peak occurrence during the adolescent growth spurt suggests a causal relationship between rapid bone growth and malignant transformation. Further evidence for this relationship is found in epidemiologic data showing patients with osteosarcoma to be taller than their peers, osteosarcoma occurring most frequently at sites where the greatest increase in length and size of bone occurs, and osteosarcoma occurring at an earlier age in girls than boys, corresponding to their earlier growth spurt. The metaphyses of long tubular bones are primarily affected. The distal femur accounts for more than 40% of cases, with the proximal tibia, proximal humerus, and mid and proximal femur following in frequency.

Clinical Findings

A. Symptoms and Signs

Pain over the involved area is the usual presenting symptom with or without an associated soft tissue mass. Patients generally have symptoms for several months prior to diagnosis. Systemic symptoms (fever, weight loss) are rare. Laboratory evaluation may reveal elevated serum alkaline phosphatase or LDH levels.

B. Imaging and Staging

Radiographic findings show permeative destruction of the normal bony trabecular pattern with indistinct margins. In addition, periosteal new bone formation and lifting of the bony cortex may create a Codman triangle. A soft tissue mass plus calcifications in a radial or sunburst pattern are frequently noted. MRI is more sensitive in defining the extent of the primary tumor and has mostly replaced CT scanning. The most common sites of metastases are the lung (≤ 20% of newly diagnosed cases) and the additional boney sites (10%). CT scan of the chest and bone scan are essential for detecting metastatic disease. PET CT may be a consideration in monitoring response to therapy. Bone marrow aspirates and biopsies are not indicated.

Despite the rather characteristic radiographic appearance, a tissue sample is needed to confirm the diagnosis. Placement of the incision for biopsy is of critical importance. A misplaced incision could preclude a limb salvage procedure and necessitate amputation. The surgeon who will carry out the definitive surgical procedure should perform the biopsy. A staging system for osteosarcoma based on local tumor extent and presence or absence of distant metastasis has been proposed, but it has not been validated.

Treatment & Prognosis

Historical studies showed that over 50% of patients receiving surgery alone developed pulmonary metastases within 6 months after surgery. This suggests the presence of micrometastatic disease at diagnosis. Adjuvant chemotherapy trials showed improved disease-free survival rates of 55%–85% in patients followed for 3–10 years.

Osteosarcomas are highly radioresistant lesions; for this reason, radiation therapy has no role in its primary management. Chemotherapy is often administered prior to definitive surgery (neoadjuvant chemotherapy). This permits an early attack on micrometastatic disease and may also shrink the tumor, facilitating a limb salvage procedure. Preoperative chemotherapy also makes detailed histologic evaluation of tumor response to the chemotherapy agents possible. If the histologic response is poor (> 10% viable tumor tissue), postoperative chemotherapy can be changed accordingly. Chemotherapy may be administered intra-arterially or intravenously, although the benefits of intra-arterial chemotherapy are disputed. Agents having efficacy in the treatment of osteosarcoma include doxorubicin, cisplatin, high-dose methotrexate, ifosfamide, and etoposide.

Definitive cure requires en bloc surgical resection of the tumor with a margin of uninvolved tissue. Amputation, limb salvage, and rotationplasty (Van Ness rotation) are equally effective in achieving local control of osteosarcoma. Contraindications to limb-sparing surgery include major involvement of the neurovascular bundle by tumor; immature skeletal age, particularly for lower extremity tumors; infection in the region of the tumor; inappropriate biopsy site; and extensive muscle involvement that would result in a poor functional outcome.

Postsurgical chemotherapy is generally continued until the patient has received 1 year of treatment. Relapses are unusual beyond 3 years, but late relapses do occur. Histologic response to neoadjuvant chemotherapy is an
excellent predictor of outcome. Patients with localized disease having 90% tumor necrosis have a 70%–85% long-term, disease-free survival rate. Other favorable prognostic factors include distal skeletal lesions, longer duration of symptoms, age older than 20 years, female gender, and near-diploid tumor DNA index. Patients with metastatic disease at diagnosis or multifocal bone lesions do not fair well, despite advances in chemotherapy and surgical techniques.

2. Ewing Sarcoma

a. General Considerations

Ewing sarcoma accounts for only 10% of primary malignant bone tumors; fewer than 200 new cases occur each year in the United States. It is a disease primarily of white males, almost never affects blacks, and occurs mostly in the second decade of life. Ewing sarcoma is considered a “small, round, blue cell” malignancy. The differential diagnosis includes rhabdomyosarcoma, lymphoma, and neuroblastoma. Although most commonly a tumor of bone, it may also occur in soft tissue (extraskeletal Ewing sarcoma or peripheral neuroectodermal tumor [PNET]).

b. Clinical Findings

A. Symptoms and Signs

Pain at the site of the primary tumor is the most common presenting sign, with or without swelling and erythema. No specific laboratory findings are characteristic of Ewing sarcoma, but an elevated LDH may be present and is of prognostic significance. Associated symptoms include fevers and weight loss.

B. Imaging and Staging

The radiographic appearance of Ewing sarcoma overlaps with osteosarcoma, although Ewing sarcoma usually involves the diaphyses of long bones. The central axial skeleton gives rise to 40% of Ewing tumors. Evaluation of a patient diagnosed as having Ewing sarcoma should include an MRI of the primary lesion to define the extent of local disease as precisely as possible. This is imperative for planning future surgical procedures or radiation therapy. Metastatic disease is present in 25% of patients at diagnosis. The lung (38%), bone (particularly the spine) (31%), and the bone marrow (11%) are the most common sites for metastasis. CT scan of the chest, bone scan, and bilateral bone marrow aspirates and biopsies are all essential to the staging workup. PET CT may be a consideration in helping to monitor therapy response.

A biopsy is essential in establishing the diagnosis. Histologically, Ewing sarcoma consists of sheets of undifferentiated cells with hyperchromatic nuclei, well-defined cell borders, and scanty cytoplasm. Necrosis is common. Electron microscopy, immunocytochemistry, and cytogenetics may be necessary to confirm the diagnosis. A generous tissue biopsy specimen is often necessary for diagnosis but should not delay starting chemotherapy.

A consistent cytogenetic abnormality, t(11;22), has been identified in Ewing sarcoma and PNET and is present in 85%–90% of tumors. These tumors also express the protooncogene c-myc, which may be helpful in differentiating Ewing sarcoma from neuroblastoma, in which c-myc is not expressed.

c. Treatment & Prognosis

Therapy usually commences with the administration of chemotherapy after biopsy and is followed by local control measures. Depending on many factors, including the primary site of the tumor and the response to chemotherapy, local control can be achieved by surgery, radiation therapy, or a combination of these methods. Following local control, chemotherapy continues for approximately 1 year. Effective treatment for Ewing sarcoma uses combinations of daunorubicin, vincristine, doxorubicin, cyclophosphamide, etoposide, and ifosfamide. Recent data showed that giving chemotherapy every 2 weeks, rather than every 3 weeks, improved the event-free survival for localized Ewing sarcoma.

Patients with small localized primary tumors have a 50%–70% long-term, disease-free survival rate. For patients with metastatic disease and large pelvic primary tumors, survival is poor. Autologous HSCT is being investigated for the treatment of these high-risk patients.

Rhabdomyosarcoma is the most common soft tissue sarcoma occurring in childhood and accounts for 10% of solid tumors in childhood. The peak incidence occurs at ages

2–5 years; 70% of children are diagnosed before age 10 years. A second smaller peak is seen in adolescents with extremity tumors. Males are affected more commonly than females.

Rhabdomyosarcoma can occur anywhere in the body. When rhabdomyosarcoma imitates striated muscle and cross-striations are seen by light microscopy, the diagnosis is straightforward. Immunohistochemistry, electron microscopy, or chromosomal analysis is sometimes necessary to make the diagnosis. Rhabdomyosarcoma is further classified into subtypes based on pathologic features: embryonal (60%–80%), of which botryoid is a variant; alveolar (about 15%–20%); undifferentiated sarcoma (8%); pleomorphic, which is seen in adults (1%); and other (11%). These subtypes occur in characteristic locations and have different metastatic potentials and outcomes.

Although the pathogenesis of rhabdomyosarcoma is unknown, in rare cases a genetic predisposition has been determined. Li-Fraumeni syndrome is an inherited mutation of the p53 tumor suppressor gene that results in a high risk of bone and soft tissue sarcomas in childhood plus breast cancer and other malignant neoplasms before age 45 years. Two characteristic chromosomal translocations [t(2;13) and t(1;13)] have been described in alveolar rhabdomyosarcoma. The t(1;13) translocation appears to be a favorable prognostic feature in patients with metastatic alveolar rhabdomyosarcoma, whereas t(2;13) is associated with poor outcomes.

► Clinical Findings

A. Symptoms and Signs

The presenting symptoms and signs of rhabdomyosarcoma result from disturbances of normal body function due to tumor growth (Table 31–9). For example, patients with orbital rhabdomyosarcoma present with proptosis, whereas patients with rhabdomyosarcoma of the bladder can present with hematuria, urinary obstruction, or a pelvic mass.

B. Imaging

A plain radiograph and a CT and/or MRI scan should be obtained to determine the extent of the primary tumor and to assess regional lymph nodes. A chest CT scan is obtained to rule out pulmonary metastasis, the most common site of metastatic disease at diagnosis. A skeletal survey and a bone scan are obtained to determine whether bony metastases are present. Bilateral bone marrow biopsies and aspirates are obtained to rule out bone marrow infiltration. Additional studies may be warranted in certain sites. For example, in parameningeal primary tumors, a lumbar puncture is performed to evaluate CSF for tumor cells.

► Treatment

Optimal management and treatment of rhabdomyosarcoma is complex and requires combined modality therapy. When feasible, the tumor should be excised, but this is not always possible because of the site of origin and size of tumor. When only partial tumor resection is feasible, the operative procedure is usually limited to biopsy and sampling of lymph nodes. Debulking of unresectable tumor may improve outcomes. Chemotherapy can often convert an inoperable tumor to a resectable one. A second-look procedure to remove residual disease and confirm the clinical response to chemotherapy and radiation therapy is generally performed at about week 20 of therapy.

Radiation therapy is an effective method of local tumor control for both microscopic and gross residual disease. It is generally administered to all patients, the only exception being those with a localized tumor that has been completely resected. All patients with rhabdomyosarcoma receive chemotherapy, even when the tumor is fully resected at diagnosis. The exact regimen and duration of chemotherapy are determined by primary site, group, and tumor node metastasis classification. Vincristine, dactinomycin, and cyclophosphamide have shown the greatest efficacy in the treatment of rhabdomyosarcoma. Newer agents such as irinotecan are also being used in the upfront treatment of metastatic rhabdomyosarcoma based on good responses in relapsed disease. Newer treatment strategies for high-risk patients include different drug combinations and dosing schedules with hematopoietic growth factor support, hyperfractionated radiation therapy, and autologous HSCT.

Prognosis
The age of the patient, the extent of tumor at diagnosis, the primary site, the pathologic subtype, and the response to treatment all influence the long-term, disease-free survival rate from the time of diagnosis. Children with localized disease at diagnosis have a 70%–75% 3-year disease-free survival rate, whereas children with metastatic disease at presentation have a worse outcome (39% 3-year disease-free survival).

Clinical Findings
A. Symptoms and Signs
Children with retinoblastoma generally come to medical attention while the tumor is still confined to the globe. Although present at birth, retinoblastoma is not usually detected until it has grown to a considerable size. Leukocoria (white pupillary reflex) is the most common sign (found in 60% of patients). Parents may note an unusual appearance of the eye or asymmetry of the eyes in a photograph. The differential diagnosis of leukocoria includes Toxocara canis granuloma, astrocytic hamartoma, retinopathy of prematurity, Coats disease, and persistent hyperplastic primary vitreous. Strabismus (in 20% of patients) is seen when the tumor involves the macula and central vision is lost. Rarely (in 7% of patients), a painful red eye with glaucoma, a hyphema, or proptosis is the initial manifestation. A single focus or multiple foci of tumor may be seen in one or both eyes at diagnosis. Bilateral involvement occurs in 20%–30% of children.
Suspected retinoblastoma requires a detailed ophthalmologic examination under general anesthesia. An ophthalmologist makes the diagnosis of retinoblastoma by the appearance of the tumor within the eye without pathologic confirmation. A white to creamy pink mass protruding into the vitreous matter suggests the diagnosis; intraocular calcifications and vitreous seeding are virtually pathognomonic of retinoblastoma. A CT scan of the orbits and MRI of the orbits/brain detects intraocular calcification, evaluates the optic nerve for tumor infiltration, and detects extraocular extension of tumor. A single focus or multiple foci of tumor may be seen in one or both eyes at diagnosis. Metastatic disease of the marrow and meninges can be ruled out with bilateral bone marrow aspirates and biopsies plus CSF cytology.

### Treatment

Each eye is treated according to the potential for useful vision, and every attempt is made to preserve vision. The choice of therapy depends on the size, location, and number of intraocular lesions. Absolute indications for enucleation include no vision, neovascular glaucoma, inability to examine the treated eye, and inability to control tumor growth with conservative treatment. External beam irradiation has been the mainstay of therapy. A total dose of 35–45 Gy is administered. However, many centers are investigating the role of systemic chemotherapy for the treatment of retinoblastoma confined to the globe and the elimination of external beam radiotherapy is now accepted. Cryotherapy, photocoagulation, and radioactive plaques can be used for local tumor control. Patients with metastatic disease receive chemotherapy.

Children with retinoblastoma confined to the retina (whether unilateral or bilateral) have an excellent prognosis, with 5-year survival rates greater than 90%. Mortality is correlated directly with extent of optic nerve involvement, orbital extension of tumor, and massive choroid invasion. Patients who have disease in the optic nerve beyond the lamina cribrosa have a 5-year survival rate of only 40%. Patients with meningeal or metastatic spread rarely survive, although intensive chemotherapy and autologous HSCT have produced long-term survivors.

Patients with the germline mutation (heritable form) have a significant risk of developing second primary tumors. Osteosarcomas account for 40% of such tumors. Second malignant neoplasms occur in both patients who have and those who have not received radiation therapy. The 30-year cumulative incidence for a second neoplasm is 35% in patients who received radiation therapy and 6% in those who did not receive radiation therapy. The risk continues to increase over time. Although radiation contributes to the risk, it is the presence of the retinoblastoma gene itself that is responsible for the development of nonocular tumors in these patients.

### HEPATIC TUMORS (SEE ALSO CHAPTER 22)

Two-thirds of liver masses found in childhood are malignant. Ninety percent of hepatic malignancies are either hepatoblastoma or hepatocellular carcinoma. Hepatoblastoma accounts for the vast majority of liver tumors in children younger than age 5 years, hepatocellular carcinoma for the majority in children aged 15–19 years. The features of these hepatic malignancies are compared in Table 31–10. Of the benign tumors, 60% are hamartomas or vascular tumors such as hemangiomas. There is mounting evidence for a strong association between prematurity and the risk of hepatoblastoma.

Children with hepatic tumors usually come to medical attention because of an enlarging abdomen. Approximately 10% of hepatoblastomas are first discovered on routine examination. Anorexia, weight loss, vomiting, and abdominal pain are associated more commonly with hepatocellular carcinoma. Serum α-fetoprotein is often elevated and is an excellent marker for response to treatment.

Imaging studies should include abdominal ultrasound, CT scan, or MRI. Malignant tumors have a diffuse hyper-echoic pattern on ultrasonography, whereas benign tumors are usually poorly echoic. Vascular lesions contain areas with varying degrees of echogenicity. Ultrasound is also useful for imaging the hepatic veins, portal veins, and inferior vena cava. CT scanning and, in particular, MRI are important for defining the extent of tumor within the liver. CT scanning of the chest should be obtained to evaluate for metastatic spread. Because bone marrow involvement is extremely rare, bone marrow aspirates and biopsies are not indicated.

The prognosis for children with hepatic malignancies depends on the tumor type and the resectability of the tumor. Complete resectability is essential for survival.
Chemotherapy can decrease the size of most hepatoblastomas. Following biopsy of the lesion, neoadjuvant chemotherapy is administered prior to attempting complete surgical resection. Monitoring the rate of decline of the alpha fetoprotein levels can help indicate favorable versus poor responders to chemotherapy. Chemotherapy can often convert an inoperable tumor to a completely resectable one and can also eradicate metastatic disease. Approximately 50%–60% of hepatoblastomas are fully resectable, whereas only one-third of hepatocellular carcinomas can be completely removed. Even with complete resection, only one-third of patients with hepatocellular carcinoma are long-term survivors. A recent CCG/Pediatric Oncology Group trial has shown cisplatin, fluorouracil, and vincristine to be as effective as but less toxic than cisplatin and doxorubicin in treating hepatoblastoma. The current open Children’s Oncology Group trial is using cisplatin, fluorouracil, vincristine, and doxorubicin along with the cardioprotectant dexrazoxane in intermediate and high risk patients. Other drug combinations that have demonstrated benefit include carboplatin plus etoposide and doxorubicin plus ifosfamide. Liver transplantation has been shown to be a successful surgical option in patients whose tumors are considered to be unresectable.

**LANGERHANS CELL HISTIOCYTOSIS**

**General Considerations**

Langerhans cell histiocytosis (LCH; formerly called histiocytosis X) is a rare and poorly understood spectrum of disorders. It can occur as an isolated lesion or as widespread systemic disease involving virtually any body site. Eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe disease are all syndromes encompassed by this disorder. LCH is not a true malignancy, but instead is a clonal, reactive proliferation of normal histiocytic cells, perhaps resulting from an immunoregulatory defect. The distinctive pathologic feature is proliferation of histiocytic cells beyond what would be seen in a normal inflammatory process. Langerhans histiocytes have typical
features: on light microscopy, the nuclei are deeply indented (coffee bean–shaped) and elongated, and the cytoplasm is pale, distinct, and abundant. Additional diagnostic characteristics include Birbeck granules on electron microscopy, expression of CD1 on the cell surface, and positive immunostaining for S-100 protein.

**Clinical Findings**

Because LCH encompasses a broad spectrum of diseases; its presentation can be variable, from a single asymptomatic lesion to widely disseminated disease.

Patients with localized disease present primarily with lesions limited to bone. Occasionally found incidentally on radiographs obtained for other reasons, these lesions are well-demarcated and frequently found in the skull, clavicles, ribs, and vertebrae. These lesions can be painful. Patients can also present with localized disease of the skin, often as a diaper rash that does not resolve.

Bony lesions, fever, weight loss, otitis media, exophthalmos, and diabetes insipidus occur in a small number of children with the disease. Children with this multifocal disease, formerly called Hand-Schüller-Christian disease, commonly present with generalized symptoms and organ dysfunction.

Children with disseminated LCH (formerly called Letterer-Siwe disease) typically present before age 2 years with a seborrheic skin rash, fever, weight loss, lymphadenopathy, hepatosplenomegaly, and hematologic abnormalities.

Diagnosis is made with biopsy of the involved organ. The workup should include a CBC, liver and kidney function tests, a skeletal survey or technetium bone scan, and a urinalysis with specific gravity to rule out diabetes insipidus.

**Treatment & Prognosis**

The outcome in LCH is extremely variable, but the process usually resolves spontaneously. Isolated lesions may need no therapy at all. Intralesional corticosteroids, curettage, and low-dose radiation therapy are useful local treatment measures for symptomatic focal lesions. Patients with localized disease have an excellent prognosis.

Multifocal disease is often treated with systemic chemotherapy. Prednisone and vinblastine are used for multifocal disease or disease involving other organs such as liver, spleen, hematopoietic system. The agents are given repeatedly or continuously until lesions heal; the drugs can then be reduced and finally stopped. A common therapeutic protocol for LCH is LCH III. Other active chemotherapeutic agents include 6-mercaptopurine, methotrexate, and etoposide. HSCT can also be used with success in refractory cases.

Multifocal disease is less predictable, but most cases resolve without sequelae. Age, degree of organ involvement, and response to therapy are the most important prognostic factors. Infants with disseminated disease tend to do poorly, with mortality rates approaching 50%. New treatment approaches for patients who do not respond to conventional chemotherapy have been evaluated in small studies. 2-Chlorodeoxyadenosine (2-CDA) has been used with some success. Therapeutic strategies targeting the dysregulated immune response using interferon-α or etanercept (anti–tumor necrosis factor-α) have also been reported.

**HEMATOPOIETIC STEM CELL TRANSPLANT**

**GENERAL CONSIDERATIONS**

Hematopoietic stem cell transplant (HSCT) is considered standard therapy for a variety of malignancies, hematopoietic disorders (aplastic anemia, hemoglobinopathies), storage diseases, and severe immunodeficiencies. In most instances, high doses of chemotherapy and/or radiation are given to the HSCT patient for myeloablation prior to infusion of stem cells that rescue marrow function. HSCT can be divided into two main categories: autologous, infusion of the patient’s own hematopoietic stem cells, or allogeneic, infusion of another individual’s (donor) hematopoietic stem cells. Stem cells can be obtained from bone marrow, peripheral blood, or umbilical cord blood.

The rationale for HSCT in patients with nonmalignant disorders is to use the transplanted donor stem cells to replace the absent or defective hematopoietic or lymphoid elements of the recipient. For children with oncologic disorders, the rationale for HSCT is multifaceted. High doses of chemotherapy and/or radiation are used to optimize tumor cell kill by overcoming cancer cell resistance. Additionally, in allogeneic HSCT (stem cells from another person), the donor lymphoid cells may recognize the cancer as foreign and provide an immunologic attack on the malignancy, a concept known as the graft-versus-tumor (GVT) effect.

Autologous transplantation, often referred to as “stem cell rescue,” is restricted to the treatment of certain pediatric...
malignancies: neuroblastoma, lymphoma, selected brain tumors, germ cell tumors, and Ewing sarcoma. Relapse of the malignancy continues to be the greatest obstacle to successful autologous transplantation, likely due to limitations in achieving systemic cancer control prior to transplant, resistance to pretreatment chemotherapy and/or radiation, and lack of GVT effect.

Allogeneic transplantation rescues hematopoiesis with stem cells from another person, either within the immediate family or an unrelated individual from a volunteer bank. Allogeneic HSCT patients require therapy to provide sufficient immunosuppression to prevent rejection of donor cells. Posttransplant medications such as cyclosporine, tacrolimus, mycophenolate, and methotrexate are needed to reduce the risk of graft-versus-host disease (GVHD). The selection of a suitable donor who matches the recipient most closely at the HLA (Human Leukocyte Antigen) loci, HLA-A, B, C, and DR, is critical, as these mediate graft rejection and GVHD. Each child expresses one set of paternal and one set of maternal HLA antigens. Thus, the probability of one child inheriting any specific combination and matching another sibling for an allogeneic transplant is one in four. Large worldwide registries of unrelated bone marrow and umbilical cord blood donors have been developed; however, finding a closely matched unrelated donor can be challenging, especially for underrepresented minorities.

Supportive care in the initial weeks after transplant includes management of chemotherapy side effects, prevention and treatment of infection, nutritional support, and immunosuppressive medications to lessen the potential for development of GVHD in allogeneic HSCT recipients. Until their new donor cells engraft, patients will also require blood product support for several weeks following preparative therapy. These blood products should be leukocyte reduced to decrease the risk of CMV transmission and irradiated to prevent GVHD from residual lymphocytes that remain even in leukocyte reduced blood products.

**HSCT COMPLICATIONS**

HSCT patients are profoundly immunocompromised for many months following transplantation and infections from bacteria, viruses, fungi, and protozoa account for significant morbidity and mortality. During the early phase (0–1 month after transplant), when there is profound neutropenia and mucosal disruption, bacteria from the patient’s aerodigestive tract are common culprits in bacteremia. Additionally, the presence of a central venous catheter makes gram-positive bacteria an important consideration. Therefore, empiric prophylactic antibiotic coverage and intravenous immune globulin supplementation are used to decrease the risk of bacterial sepsis. Acyclovir prophylaxis is used to prevent the reactivation of herpes simplex virus that may occur early in up to 70% of seropositive patients, while antifungal agents are routinely used to prevent infections from *Candida* and *Aspergillus* (Figure 31–1).

In the intermediate phase (1–6 months after transplant), the HSCT patient usually has adequate neutrophil counts yet remains significantly compromised due to reduced T-lymphocyte cell number and function. Because of this relative T-cell defect a child after transplant is susceptible to sudden, overwhelming illness from viral pathogens. CMV reactivation or new infection is relatively common and can result in retinitis, enteritis, and pneumonia. Treatment with foscarnet or ganciclovir is usually successful if CMV infection is recognized early particularly when preventive or preemptive approaches to control viremia are used. Common community acquired viruses, such as respiratory syncytial virus, adenovirus, influenza, parainfluenza, and human metapneumovirus can also be life-threatening therefore prevention is critical. The use of frequent hand washing, contact restriction, and early treatment with available antiviral therapies, such as inhaled ribavirin, can be lifesaving in this population. Prophylactic administration of acyclovir helps limit reactivation of herpes simplex virus and varicella-zoster virus (shingles). Trimethoprim-sulfamethoxazole, dapsone, or pentamidine prophylaxis reduces, but does not eliminate, *P jiroveci pneumonia*. The late phase (6–12 months after transplant) is characterized by dysfunction of the reticuloendothelial system, leading to infections from encapsulated bacteria such as pneumococcus, and ongoing inadequate lymphocyte function, resulting in poor control of viral infection and reactivation. Patients on immunosuppressive treatment for GVHD have an increased and protracted risk of all types of infections.

Graft versus host disease results when donor lymphocytes recognize the recipient tissues as foreign and mount an immunologic attack. Despite the use of immunosuppressive agents, anti-T-cell antibodies, and T-cell depletion of the donor graft, 20%–70% of allogeneic HSCT patients experience some degree of acute GVHD. Factors influencing GVHD risk include the degree of HLA match, stem cell source, patient age, and donor sex. Acute GVHD generally occurs within the first 100 days after transplant but on occasion, may occur later. Acute GVHD typically presents with a maculopapular skin rash, secretory diarrhea, and/or cholestatic jaundice. Chronic GVHD generally occurs after day 100 and may involve multiple organ systems. Sclerotic skin, malabsorption, weight loss, keratoconjunctivitis sicca, oral mucositis, chronic lung disease, and cholestatic jaundice are common manifestations. Treatment for GVHD consists of further use of immunosuppressive agents.

Long-term follow-up of HSCT patients is essential. Patients are at risk for numerous complications, including pulmonary disease, cataracts, endocrine dysfunction affecting growth and fertility, cardiac dysfunction, avascular necrosis of bone, developmental delay, and secondary malignancies. Although HSCT has many challenges, it represents an important advance in curative treatment for a variety of serious pediatric illnesses.
Late effects of treatment by surgery, radiation, and chemotherapy have been identified in survivors of pediatric cancer. Current estimates are that 1 in every 640 adults between the ages of 20 and 39 years is a pediatric cancer survivor. One recent study found that 60% of survivors of pediatric cancer diagnosed between 1970 and 1986 have at least one chronic condition. Virtually any organ system can demonstrate sequelae related to previous cancer therapy. This has necessitated the creation of specialized oncology clinics whose function is to identify and provide treatment to these patients.

The Childhood Cancer Survivor Study, a pediatric multi-institutional collaborative project, was designed to investigate the various aspects of late effects of pediatric cancer therapy in a cohort of over 13,000 survivors of childhood cancer.
GROWTH COMPLICATIONS

Children who have received cranial irradiation are at highest risk of developing growth complications. Growth complications of cancer therapy in the pediatric survivor are generally secondary to direct damage to the pituitary gland, resulting in growth hormone deficiency. However, new evidence in children treated for ALL suggests that chemotherapy alone may result in an attenuation of linear growth without evidence of catch-up growth once therapy is discontinued. Up to 90% of patients who receive more than 30 Gy of radiation to the CNS will show evidence of growth hormone deficiency within 2 years. Approximately 50% of children receiving 24 Gy will have growth hormone problems. The effects of cranial irradiation appear to be age-related, with children younger than age 5 years at the time of therapy being particularly vulnerable. These patients usually benefit from growth hormone therapy. Currently, there is no evidence that such therapy causes a recurrence of cancer.

Spinal irradiation inhibits vertebral body growth. In 30% of treated children, standing heights may be less than the fifth percentile. Asymmetrical exposure of the spine to radiation may result in scoliosis.

Growth should be monitored closely, particularly in young survivors of childhood cancer. Obesity may become an issue for selected survivors who are young at diagnosis and have received whole brain radiation. Follow-up studies should include height, weight, growth velocity, scoliosis examination, and, when indicated, growth hormone testing.

ENDOCRINE COMPLICATIONS

Thyroid dysfunction, manifesting as hypothyroidism, is common in children who received total body irradiation, cranial irradiation, or local radiation therapy to the neck and/or mediastinum. Particularly at risk are children with brain tumors who received more than 3000 cGy and those who received more than 4000 cGy to the neck region. The average time to develop thyroid dysfunction is 12 months after exposure, but the range is wide. Therefore, individuals at risk should be monitored yearly for at least 7 years from the completion of therapy. Although signs and symptoms of hypothyroidism may be present, most patients will have a normal thyroxine level with an elevated thyroid-stimulating hormone level. These individuals should be given thyroid hormone replacement because persistent stimulation of the thyroid from an elevated thyroid-stimulating hormone level may predispose to thyroid nodules and carcinomas. In a recent report from the Childhood Cancer Survivor Study, thyroid cancer occurred at 18 times the expected rate for the general population in pediatric cancer survivors who received radiation to the neck region. Hyperthyroidism, although rare, also occurs in patients who have received neck irradiation.

Precocious puberty, delayed puberty, and infertility are all potential consequences of cancer therapy. Precocious puberty, more common in girls, is usually a result of cranial irradiation causing premature activation of the hypothalamic-pituitary axis. This results in premature closure of the epiphysis and decreased adult height. Luteinizing hormone analogue and growth hormone are used to halt early puberty and facilitate continued growth.

Gonadal dysfunction in males is usually the result of radiation to the testes. Patients who receive testicular irradiation as part of their therapy for ALL, abdominal irradiation for Hodgkin disease, or total body irradiation for HSCT are at highest risk. Radiation damages both the germinal epithelium (producing azoospermia) and Leydig cells (causing low testosterone levels and delayed puberty). Alkylation agents such as ifosfamide and cyclophosphamide can also interfere with male gonadal function, resulting in oligospermia or azoospermia, low testosterone levels, and abnormal follicle-stimulating hormone (FSH) and luteinizing hormone (LH) levels. Determination of testicular size, semen analysis, and measurement of testosterone, FSH, and LH levels will help identify abnormalities in patients at risk. When therapy is expected to result in gonadal dysfunction, pretherapy sperm banking should be offered to adolescent males.

Exposure of the ovaries to abdominal radiation may result in delayed puberty with a resultant increase in FSH and LH and a decrease in estrogen. Girls receiving total body irradiation as preparation for HSCT and those receiving craniospinal irradiation are at particularly high risk for delayed puberty as well as premature menopause. In patients at high risk for development of gonadal complications, a detailed menstrual history should be obtained, and LH, FSH, and estrogen levels should be monitored if indicated.

No studies to date have confirmed an increased risk of spontaneous abortions, stillbirths, premature births, congenital malformations, or genetic diseases in the offspring of childhood cancer survivors. Women who have received abdominal irradiation may develop uterine vascular insufficiency or fibrosis of the abdominal and pelvic musculature or uterus, and their pregnancies should be considered high risk.

CARDIOPULMONARY COMPLICATIONS

Pulmonary dysfunction generally manifests as pulmonary fibrosis. Therapy-related factors known to cause pulmonary toxicities include certain chemotherapeutic agents, such as bleomycin, the nitrosoureas, and busulfan, as well as lung or total body irradiation. Pulmonary toxicity due to chemotherapy is related to the total cumulative dose received. Pulmonary function tests in patients with therapy-induced toxicity show restrictive lung disease, with decreased carbon monoxide diffusion and small lung volumes. Individuals exposed to these risk factors should be counseled to refrain...
from smoking and to give proper notification of the treatment history if they should require general anesthesia.

Cardiac complications usually result from exposure to anthracyclines (daunorubicin, doxorubicin, and mitoxantrone), which destroy myocytes and lead to inadequate myocardial growth as the child ages, and eventually result in congestive heart failure. The incidence of anthracycline cardiomyopathy increases in a dose-dependent fashion. A recent report indicates that survivors receiving cumulative doses larger than 360 mg/m$^2$ were more than 40 times more likely to die of cardiac disease. In a recent study, complications from these agents appeared 6–19 years following administration of the drugs. Pregnant women who have received anthracyclines should be followed closely for signs and symptoms of congestive heart failure, as peripartum cardiomyopathy has been reported.

Radiation therapy to the mediastinal region, which is a common component of therapy for Hodgkin disease, has been linked to an increased risk of coronary artery disease; chronic restrictive pericarditis may also occur in these patients.

Current recommendations include an echocardiogram and electrocardiogram every 1–5 years, depending on the age at therapy, total cumulative dose received, and presence or absence of mediastinal irradiation. Selective monitoring with various modalities is indicated for those who were treated with anthracyclines when they were younger than age 4 years or received more than 500 mg/m$^2$ of these drugs. Biomarkers such as cardiac troponins and brain natriuretic peptides may be useful in assessing cardiotoxicity of anthracyclines.

**RENAL COMPLICATIONS**

Long-term renal side effects stem from therapy with cisplatin, alkylating agents (ifosfamide and cyclophosphamide), or pelvic irradiation. Patients who have received cisplatin may develop abnormal creatinine clearance, which may or may not be accompanied by abnormal serum creatinine levels, as well as persistent tubular dysfunction with hypomagnesemia. Alkylating agents can cause hemorrhagic cystitis, which may continue after chemotherapy has been terminated and has been associated with the development of bladder carcinoma. Ifosfamide can also cause Fanconi syndrome, which may result in clinical rickets if adequate phosphate replacement is not provided. Pelvic irradiation may result in abnormal bladder function with dribbling, frequency, and enuresis.

Patients seen in long-term follow-up who have received nephrotoxic agents should be monitored with urinalysis, appropriate electrolyte profiles, and blood pressure. Urine collection for creatinine clearance or renal ultrasound may be indicated in individuals with suspected renal toxicity.

**NEUROPSYCHOLOGICAL COMPLICATIONS**

Pediatric cancer survivors who have received cranial irradiation for ALL or brain tumors appear to be at greatest risk for neuropsychological sequelae. The severity of cranial irradiation effects varies among individual patients and depends on the dose and dose schedule, the size and location of the radiation field, the amount of time elapsed after treatment, the child’s age at therapy, and the child’s gender. Girls may be more susceptible than boys to CNS toxicity because of more rapid brain growth and development during childhood.

Auditory complications can be seen in childhood cancer survivors exposed to platinum-based chemotherapy and/or temporal or posterior fossa radiation. Difficulty hearing sounds, tinnitus, or hearing loss requiring an aid have been reported.

The main effects of CNS irradiation appear to be related to attention capacities, ability with nonverbal tasks and mathematics, and short-term memory. Recent studies support the association between treatment with high-dose systemic methotrexate, triple intrathecal chemotherapy, and, more recently, dexamethasone and more significant cognitive impairment.

Additionally, pediatric cancer patients have been reported as having more behavior problems and as being less socially competent than a sibling control group. Adolescent survivors of cancer demonstrate an increased sense of physical fragility and vulnerability manifested as hypochondriasis or phobic behaviors.

A recent report from Childhood Cancer Survivor Study noted that when compared to population norms, childhood cancer survivors and siblings report positive psychological health, good health-related quality of life, and life satisfaction. There are, however, subgroups that could be targeted for intervention.

**SECOND MALIGNANCIES**

Approximately 3%–12% of children receiving cancer treatment will develop a new cancer within 20 years of their first diagnosis. This is a 10-fold increased incidence when compared with age-matched control subjects. Particular risk factors include exposure to alkylating agents, epipodophyllotoxins (etoposide), and radiation therapy, primary diagnosis of retinoblastoma or Hodgkin disease, or the presence of an inherited genetic susceptibility syndrome (Li-Fraumeni syndrome or NF). In a recent report, the cumulative estimated incidence of second malignant neoplasms for the cohort of the Childhood Cancer Survivor Study was 3.2% at 20 years from diagnosis.

Second hematopoietic malignancies (acute myelogenous leukemia) occur as a result of therapy with epipodophyllotoxins or alkylating agents. The schedule of drug
administration (etoposide) and the total dose may be related to the development of this secondary leukemia.

Children receiving radiation therapy are at risk for developing second malignancies, such as sarcomas, carcinomas, or brain tumors, in the field of radiation. A recent report examining the incidence of second neoplasms in a cohort of pediatric Hodgkin disease patients showed the cumulative risk of a second neoplasm to be as high as 8% at 15 years from diagnosis. The most common solid tumor was breast cancer (the majority located within the radiation field) followed by thyroid cancer. Girls aged 10–16 years when they received radiation therapy were at highest risk and had an actuarial incidence that approached 35% by age 40 years. Secondary gastrointestinal cancer is also increased in pediatric cancer survivors and is related to radiation exposure as well as to certain types of chemotherapeutic agents (procarbazine, platinums).

Children experience pain to at least the same level as adults. Multiple studies have shown that neonates and infants perceive pain and have memory of these painful experiences. Frequently, children are underprescribed and underdosed for opioid and nonopioid analgesics due to excessive concerns of respiratory depression and/or poor understanding of the need for pain medications in children. Few data are available to guide the dosing of many pain medications and the majority of pain medications available on the market today are unlabeled for use in pediatric patients.

Pain Management & Pediatric Palliative & End-of-Life Care

ACUTE PAIN

Definition Etiology
Acute pain is caused by an identifiable source. In most cases, it is self-limiting and treatment is a reflection of severity and type of injury. In children, the majority of acute pain is caused by trauma or, if in a hospital setting, an iatrogenic source such as surgery.

Treatment
Treatment of acute pain is dependent on the disposition of the individual patient. For outpatient care the mainstay of treatment is nonsteroidal anti-inflammatory drugs (NSAIDs) (Table 32–3). Acetaminophen is the most commonly used NSAID. Acetaminophen is administered via the oral or rectal routes. Acetaminophen is more predictable in its effects as an oral dose. It has also been found that round-the-clock administration (oral 10–15 mg/kg, rectal 20 mg/kg) is better than PRN dosing for both minor pain or as an adjunct for major pain. The toxicity of acetaminophen is low in clinically used doses. However, the use of acetaminophen combined with many over-the-counter and prescription combination products has been a frequent cause of toxicity. Liver damage or failure can occur with doses exceeding 200 mg/kg/d. Other oral analgesics available in suspension are ibuprofen (10–15 mg/kg) and naproxen (10–20 mg/kg).
When pain is more severe, oral opioids can be added for short-term use (Table 32–4). Many of these opioids come formulated with an NSAID, that is, oxycodone/acetaminophen (Percocet) and hydrocodone/acetaminophen (Lortab). When using these combination drugs, the dose of drug is based on the opioid component. Other concomitantly administered similar NSAIDs should be discontinued. The most commonly used oral opioids are oxycodone, hydrocodone, and codeine. The use of codeine is least recommended due to its metabolism. Codeine is metabolized to morphine via the cytochrome P-450 2D4 isoenzyme. From 1% to 10% people (Asians 1%–2%, African Americans 1%–3%, Caucasians 5%–10%) are poor metabolizers as a result of a genetic polymorphism. Thus, patients with this

Whenever PCA is used, it is imperative to assess patients frequently (at least hourly) to ensure adequate pain relief.

**CHRONIC PAIN MANAGEMENT**

**Assessment**

Chronic pain is a pain that persists past the usual course of an acute illness or beyond the time that is expected for an acute injury. In children this is an increasingly recognized problem. It is estimated that chronic pain may affect as much as 10%–15% of the population. The most common problems include headache, chronic abdominal pain, myofascial pain, fibromyalgia, juvenile rheumatoid arthritis, complex regional pain syndrome, phantom limb pain, and pain associated with cancer. Chronic pain in children...

often has multiple other contributing factors, including psychological issues, psychosocial factors, sociologic factors, and family dynamics. Associating pain with a single physical cause can lead the physician to investigate the patient with repeated invasive testing, laboratory tests, and procedures and to overprescribe medications. A multidimensional assessment to chronic pain is optimal and often required.

Treatment

When possible, a multidisciplinary team approach is standard of care for treating chronic pain in children. All children evaluated for chronic pain should be seen on their initial visit by all primary members of the team to establish a management strategy. Team members should include a pain physician, a pediatric psychologist and/or a psychiatrist, occupational and physical therapists (OT/PT), advanced pain nurses (APNs), and a social worker. The majority of pediatric chronic pain management programs in the United States base their approach on combined intensive rehabilitation and intensive psychotherapy relying minimally on invasive procedures and pharmacotherapy.

A. Tolerance, Dependence, and Addiction

Physiologic and psychological responses to opioids are similar between adults and children. A consensus paper by the American Academy of Pain Medicine, American Pain Society, and American Society of Addiction Medicine defined important differences between normal and pathologic responses to opioids. The definitions of tolerance dependence and addiction are listed below.

1. Tolerance—A state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drug’s effects over time. Tolerance develops at different rates for different opioid effects, that is, tolerance to sleepiness and respiratory depression occurs earlier than that to constipation and analgesia.

2. Dependence—A state of adaptation that is manifested by a drug class-specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist.

3. Addiction—A primary, chronic, neurobiologic disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following:
   • Loss of Control over use of drug
   • Craving and Compulsive use of drug
   • Use despite adverse Consequences

Addiction is rare when opioids are used appropriately for acute pain on both inpatient and outpatient settings. It should be emphasized that tolerance and dependence do not equal addiction.

B. Withdrawal

1. Recognition—Withdrawal symptoms can be expected to occur for all patients after 1 week of opioid treatment. Signs of withdrawal in older children include agitation, irritability, dysphoria, tachycardia, tachypnea, nasal congestion, temperature instability, and feeding intolerance. In neonates with withdrawal (neonatal abstinence syndrome), common symptoms include neurologic excitability, gastrointestinal dysfunction, autonomic signs (increased sweating, nasal stuffiness, fever, mottling, poor weight gain), and skin excoriation secondary to excessive rubbing.

2. Treatment
   • Make a schedule/plan in conjunction with patient and family.
   • Factor in duration of time on opioid.
   • Consider switching to once-a-day opioid (see methadone dosing in Table 32–4).
   • Decrease the dose by 10%–25% every 1–2 days.
   • Look for signs of withdrawal.
   • Consider adding lorazepam 0.05–0.1 mg/kg every 6–8 hours.
   • Consider adding clonidine patch 0.1 mg/d (changed every fifth day).

PEDIATRIC PALLIATIVE & END-OF-LIFE CARE

INTRODUCTION

It has been estimated that almost 55,000 children die each year in the United States. At least 50% of these children die during the newborn period or within the first year of life. Many of these children, particularly those older than 1 year of age, suffer from illnesses that are clearly life-limiting. Thousands more children are diagnosed with life-limiting illnesses, resulting in a chronic condition that may last for many years, even decades. Furthermore, children who are diagnosed with life-threatening illnesses may be curable, such as cancer, continue to live with the potential of a recurrence of their malignancy for many years. The above populations are those where palliative and end-of-life care could play an important role during the illness of these patients.

Although commonly used interchangeably, palliative care and end-of-life care are not synonymous terms.
Palliative care aims to prevent, relieve, reduce, or soothe the symptoms produced by potential life-limiting illnesses or their treatments and to maintain the patient’s quality of life along the entire continuum of treatment. Provision of palliative care does not imply imminent death nor does it prohibit aggressive curative treatment modalities. Rather, it acknowledges the uncertainty and potential for suffering inherent in a potentially life-limiting condition such as cancer. Understanding how a family defines quality of life and suffering for their child is imperative and provides a framework for decision making between care provider and the family throughout treatment.

While a child is doing well with treatment, the primary focus will be on achieving cure or stabilization of the disease. Palliative care goals at this time focus on promoting quality of life in preparation for survivorship in the face of a potentially life-limiting illness. Some of these goals include helping a family come to terms with the diagnosis, addressing issues of treatment-related pain and distress, facilitating reintegration into the social realms of school and community, and promoting as much normalcy in the child’s life as possible. When it becomes clear that the chances for cure are poor or present an unreasonable cost to the child’s quality of life, the goals of palliative care will shift toward end-of-life care. The focus will still be on promoting quality of life but now in preparation for a comfortable and dignified end of life with increasingly less attention given to the treatment or cure of the disease itself.

When initiating a palliative or end of life care discussion with a patient and family it is important to keep in mind some useful guidelines such as choice of a quiet setting, avoidance of interruptions, assessment of family’s and patient’s perception of the situation, giving useful information to the patient and family, addressing emotional responses, and planning for next steps.

Palliative care not only comprises support in the pain and symptom management of the disease but also addresses equally the psychosocial, emotional, and spiritual needs of the patient with a potential life-limiting illness and their family.

**CHILDREN WHO MAY BENEFIT FROM PALLIATIVE CARE INTERVENTIONS**

In a recent review by Himelstein et al, conditions that are appropriate for palliative care were divided into four groups as follows:

1. **Conditions for which curative treatment is possible but may fail such as advanced or progressive cancer and complex and severe congenital or acquired heart disease**

2. **Conditions requiring intensive long-term treatment aimed at maintaining the quality of life such as HIV/AIDS, cystic fibrosis, and muscular dystrophy**

3. **Progressive conditions in which treatment is exclusively palliative after diagnosis such as progressive metabolic disorders and certain chromosomal abnormalities**

4. **Conditions involving severe, nonprogressive disability, causing extreme vulnerability to health complications such as severe cerebral palsy and anoxic brain injury**

The United States Congress mandated in 2010 that palliative care will be covered concurrently with curative therapies for children with terminal conditions who are receiving Medicaid. Based on the *Patient Protection and Affordable Care Act*, a voluntary election to receive hospice care for a child does not constitute a waiver of any rights of the child to be provided with, or to have payments made for services that are related to the treatment of the child’s condition. This significant milestone in pediatric palliative care should open the door to concurrent care being covered by private insurance companies in the future.

**PAIN MANAGEMENT IN PEDIATRIC PALLIATIVE CARE**

Optimal pain management is critical when providing pediatric palliative care. (See the section on pain management earlier, for definitions and guidelines for treatment.) As end of life approaches, dosing of comfort medications may eventually exceed normally prescribed doses. The goal at all times must be to achieve and maintain comfort. When pain management at the end of life is provided with this goal at the forefront and in concert with careful ongoing assessment and documentation of the child’s symptoms, there should be no reason to fear that this action is tantamount to euthanasia which is a conscious action intended to hasten death.

**QUALITY-OF-LIFE ADJUNCTS & SYMPTOM MANAGEMENT IN PÉDIA TRIC PALLIATIVE CARE**

When offering treatment to children with a life-limiting illness particularly at the end of life, certain nonpain symptoms and signs may develop more quickly in children when compared to the adult population. A thorough and complete history and physical examination should be obtained. It is critical to determine how much distress the symptom causes the child and how much it interferes with child and family’s routine when deciding upon treatment. Areas of management should include drug treatment, nursing care, and psychosocial support. Symptoms that commonly occur during disease progression and at the end of life in children with a life-limiting condition are listed in Table 32–6, with suggestions for management.

**Complementary & Alternative Modalities**

It is not unusual for families seek complementary or alternative modalities (CAM) for their child when mainstream
As children approach end of life, many families opt to try some form of CAM. The most common modalities reported in pediatrics are prayer/meditation, relaxation techniques, massage, chiropractic care including acupuncture, and nutritional supplements. The use of CAM in children is influenced primarily by parental use and acceptance of CAM. Culturally accepted beliefs and practices also play an important role. In Asia, the use of meditation and prayer as a method to control pain is well supported by the medical community. In Europe, the use of homeopathic remedies is commonplace.

</table>
Studies of the effectiveness of CAM use in children have been small and the data is often conflicting. There is generally an acceptance for the lack of harm associated with mind–body techniques such as prayer, meditation, touch and sensory modalities, and relaxation. Acupuncture and acupressure are gaining more acceptance in the Western medical community and may be beneficial in some children for relief of pain, nausea, and other symptoms. Touch and sensory modalities such as massage, Healing Touch, and aromatherapy can induce a relaxation response in some children which can be very helpful. The use of supplements including botanicals and vitamins has been of more concern due to the lack of dosing information for pediatrics and the potential for serious drug interactions and toxicities. Treatments touted as alternative “cures” are likely not beneficial and can have very dangerous consequences. The cost of CAM, particularly botanicals and alternative medicine treatments, can be prohibitive and the cost is rarely covered by insurance. Hospice providers frequently incorporate relaxation and mind/body/spirit modalities into their programs.

It is important for the healthcare provider to ask parents and adolescents about CAM usage and to be open to discussion with the family about modalities they are using or may wish to consider. Parents consistently have reported in studies their desire to inform and discuss CAM with their healthcare provider, but may be reluctant to do so if they are unsure what response they will get from the provider. Providing families with clear information about the treatment they are considering or using and any contraindications is key. In some cases, recommendation of complementary techniques such as massage, mind/body modalities, and acupuncture/acupressure may be appropriate.

**PSYCHOSOCIAL ASPECTS OF PEDIATRIC PALLIATIVE CARE**

Pediatric palliative care is unique in that caregivers must be familiar with children’s normal emotional and spiritual development. Working with a child at his or her level of development through the use of both oral and expressive communication will allow the child to be more open with respect to hopes, dreams, and fears. A child’s understanding of death will depend also on his or her stage of development. Children understand death as a changed state by 3 years of age, universality by 5–6 years of age, and personal mortality by 8–9 years of age. Table 32–7 gives a broad overview of children’s concepts of death and offers some helpful interventions.

**CHILDREN’S CONCEPT OF DEATH**

As end of life approaches, psychosocial support is invaluable to the child and family. Children may need someone to talk to outside of the family unit who can respond to their questions and concerns openly and honestly. Parents may need guidance and support in initiating discussions with or responding to questions from their child about death and dying. Children and adolescents may have specific tasks they wish to complete before they die. Some want to have input into funeral and memorial service plans and disposition of their body. Parents often need support in making funeral arrangements, handling financial concerns, talking with siblings and other family members, and coping with their own grief.

It is important to recognize that grief is not an illness but a normal, multidimensional, unique, dynamic process presenting as pervasive distress due to a perceived loss. Once parents have accepted the reality of the loss of the child, they must then complete the other tasks of grief such as experiencing the pain of their loss and adjusting to an environment without their child in order to move on with their lives. Parents who lose a child are at high risk for complicated grief reactions such as absent grief, delayed grief, and prolonged or unresolved grief. Siblings are also at risk for complicated grief and require special attention.

**SPIRITUAL & CULTURAL SUPPORT**

Healthcare decisions are often intertwined with a family’s culture and belief system. Understanding the influences of a family’s beliefs and culture allows the practitioner to provide sensitive, appropriate care, particularly at the end of life. Interaction with members of the family’s faith and cultural communities can often be instrumental in helping both the care team and the community support of the family. Allowing for specific prayers, rituals, or other activities may help facilitate procedures and discussions.

Families who speak a foreign language probably suffer from inadequate support the most. Every effort should be made to find and utilize a qualified interpreter, particularly for any discussion that involves delivering difficult news or making critical decisions. Many times, the role of interpreter is imposed upon a bilingual family member or friend who may not understand medical terminology well enough to translate clearly or who may deliberately translate the information inaccurately in an attempt to protect the family.

**WITHDRAWAL OF MEDICAL LIFE SUPPORT**

Medical technology has enabled many children with serious health conditions to enjoy a good quality of life. When technological support no longer enables a child’s quality and enjoyment of life or there are no viable options to restore quality of life to the child, it may be appropriate to discontinue it. Feeding tubes, ventilators, dialysis, parenteral nutrition, and implanted cardiac pacemakers are examples of medical modalities that may need to be reevaluated when a child’s condition deteriorates or in the case of a catastrophic injury.
There are five circumstances in which withdrawal of medical support and technology can be considered in children (Tournay, 2000) (see the table below).

At these times, it will be necessary to have a gentle but frank and honest discussion with the family that includes listening to their understanding of the child’s situation and prognosis. Helping them identify and define what quality of life means to their child and to the family and what would be an intolerable life for the child is important. It is critical to present in a clear and understandable format the child’s medical condition, test results, and the treatments that have been tried, what the expectations are for the child’s ability to survive or function and interact with his environment, and why it is believed that current or additional interventions will be futile or induce further suffering. These discussions should be conducted with sensitivity and without need for an immediate answer from the parents. It often takes several such discussions for families to come to a decision that they themselves will be able to live with and families should not be rushed into decision making. The family may request

Considered decision makers are identified and included in care planning as a four-step process. First, those individuals known their wishes about what to do in case of serious or life-threatening problems. Himelstein et al describe advance care planning allows patients and families to make decisions about end-of-life care while they are still able to do so. This process involves discussing end-of-life wishes and preferences, documenting these decisions in an advance directive, and sharing these decisions with healthcare providers, family members, and others involved in the patient’s care.

**ADVANCE CARE PLANNING**

Advance care planning allows patients and families to make known their wishes about what to do in case of serious or life-threatening problems. Himelstein et al describe advance care planning as a four-step process. First, those individuals considered decision makers are identified and included in the process. Second, an assessment of the patient’s and family’s understanding of the illness and prognosis is made and the impending death is described in terms that the child and family can understand. Third, on the basis of their understanding of the illness and prognosis, the goals of care are determined regarding current and future intervention—curative, uncertain, or primarily focused on providing comfort. Finally, shared decisions about the current and future use or abandonment of life-sustaining techniques and aggressive medical interventions are made. In the event of a disagreement between parents or parents and patient regarding these techniques or interventions, it may be prudent to involve the hospital’s ethics committee in order to resolve these issues.

Some states permit parents to sign an advanced directive that asserts their decision not to have resuscitative attempts made in the event of a cardiac or respiratory arrest outside of the hospital. When an advanced directive is in place, emergency responders are not required to provide cardio-pulmonary resuscitation (CPR) if called to the scene. Some school districts will respect an advanced directive on school property, many will not. If a child with an advanced directive in place wishes to go to school, a discussion between the medical team and school officials should be arranged to determine the best plan should the child have a cardiac or respiratory arrest at school.

Parents and, occasionally, the child may bring up the possibility of donating organs or body tissues after death. Although the tissues that may be donated by a child may be limited in some instances by the type of disease (eg, cancer), some parents find immense comfort in knowing their child was able to benefit another. If the parents have not discussed donation with the physician by the time of death and donation is possible, the physician should offer the opportunity to the family.

Autopsy is another subject many physicians find difficult to approach with a family, but it is an important option to discuss. In cases of anticipated death from natural causes, autopsies are generally not mandatory; however, information obtained from an autopsy may be useful for parental peace of mind or medical research. If death at home is to be followed by an autopsy, special arrangements for transporting and receiving the body will need to be made with the mortuary or the coroner.

Immune deficiencies that present in childhood comprise rare disorders that have been characterized by a combination of clinical patterns, immunologic laboratory tests, and often molecular identification of the mutant gene. Children with primary immunodeficiency (PID) commonly present with recurrent and/or severe bacterial infections, failure to thrive, and/or developmental delay as a result of infection. Immunodeficiency should be considered when infections are recurrent, severe, persistent, resistant to standard treatment, or caused by opportunistic organisms. Because delayed diagnosis of PIDs is common, heightened diagnostic suspicion is warranted.

The human immune system consists of the phylogenetically more primitive innate immune system and the adaptive immune system. For the purpose of clinical categorization, PIDs are commonly divided into four main groups: antibody deficiencies, combined T- and B-cell immunodeficiencies, phagocyte disorders, and complement deficiencies. Understanding the role each part of the immune system plays in host defense allows critical evaluation for possible immunodeficiency as the cause of recurrent infections.

**IMMUNODEFICIENCY EVALUATION: PRIMARY CONSIDERATIONS**

When evaluating for a possible PID, other conditions that increase susceptibility to infections have to be considered, such as allergic rhinitis, asthma, cystic fibrosis, foreign body aspiration, and conditions that interfere with skin barrier function. Common causes of secondary or acquired immunodeficiency need to be excluded. These include malnutrition, aging, certain drugs (chemotherapy, immunosuppressive medications, glucocorticoids, disease-modifying antirheumatic drugs, rituximab), protein loss via gastroenteropathy or kidney disease, and other diseases associated with impaired immunity (bone marrow and blood cell malignancies, and certain chronic infections, including AIDS). If a single site is involved, anatomic defects and foreign bodies may be present. Figure 33–1 outlines when PIDs should be considered.

Key clinical patterns can indicate the presence of a PID and the category of immune impairment. Frequency, severity, and age of onset of infections are important clues. The Modell Foundation warning signs for PID are shown in Figure 33–2. Children who meet two or more of these signs should be screened for PID. The type of infections should guide initial investigation, as antibody, complement, and phagocyte defects predispose mainly to bacterial infections, but diarrhea, superficial candidiasis, opportunistic infections, and severe herpesvirus infections are more characteristic of T-lymphocyte immunodeficiency. Combined immunodeficiency syndromes will present with a combination of infections typical for B- and T-lymphocyte deficiencies. Table 33–1 classifies PID into four main host immunity categories based on age of onset, infections with specific pathogens, affected organs, and other special features. Finally, male gender increases the likelihood of an X-linked (XL) PID, while consanguinity increases the likelihood of an autosomal recessive (AR) form of PID.

Research on deficiencies of the innate immune response is an evolving field. Pattern-recognition receptors (PRRs) are important for the recognition of pathogen-associated molecular patterns specific for different microbes, initiation of the innate immune response, and cross talk with adaptive immunity. They are expressed on the surface or in the cytoplasm of cells of the innate immune system, dependent on where specific microbes are encountered. Four classes of PRRs have been identified. Toll-like receptors (TLRs) recognize a spectrum of bacteria, viruses, selected fungi, and protozoa. C-type lectin receptors (CLR) that include dectin-1 and mannose-binding lectin are involved in recognition of bacteria and fungi. Cytoplasmic PRRs include nucleotide-binding oligomerization domain (NOD) leucine-rich-repeat containing receptors (NLRs) that recognize peptidoglycan structures on bacteria, and retinoic acid-inducible gene I protein (RIG-1) helicase receptors that recognize viral nucleic acids. Dependent on the defect in PRR signaling, patients may present with an increased susceptibility of bacterial, viral, or fungal infections.
Chapter 3

Figure 33–1. General approach to primary immunodeficiencies.

Step 1: “Too many” infections. See Figure 33–2 for warning signs.

Step 2: Rule out common causes of infection (asthma, foreign body) and secondary immunodeficiency (malnutrition, HIV).

Step 3: Consider primary immunodeficiencies—specifically considering types and locations of infections, age of child, and other associated findings. See Table 33–1 for details.

Step 4: Categorize the patient and order screening tests. See Table 33–2 for more details.

Step 5: Consider referral to immunology specialist and secondary laboratory tests.

Figure 33–2. Warning signs of primary immunodeficiency. (Data from the Jeffrey Modell Foundation.)

10 Warning signs of primary immunodeficiency

Primary immunodeficiency (PID) causes children and young adults to have infections that come back frequently or are unusually hard to cure. In America alone, up to 1/2 million people suffer from one of the 100 known PID diseases. If you or someone you know are affected by two or more of the following warning signs, speak to a physician about the possible presence of an underlying PID.

1. Eight or more new ear infections in 1 y.
2. Two or more serious sinus infections within 1 y.
3. Two or more months on antibiotics with little effect.
4. Two or more pneumonias within 1 y.
5. Failure of an infant to gain weight or grow normally.
6. Recurrent, deep skin or organ abscesses.
7. Persistent thrush in mouth or elsewhere on skin, after age 1.
8. Need for intravenous antibiotics to clear infections.
9. Two or more deep-seated infections.
10. A family history of primary immunodeficiency.
### Table 33–1. Clinical features of primary immunodeficiencies.

Laboratory investigation should be directed by the clinical presentation and the suspected category of host immunity impairment. A complete blood cell count (CBC) with cell differential and measurement of quantitative immunoglobulins (Igs) will identify the majority of patients with PID, as antibody deficiencies account for at least 50% of PIDs (Figure 33–3). Table 33–2 summarizes the approach to laboratory evaluation of PID.

### Antibodies & Immunoglobulins

The initial laboratory screening for antibody deficiency includes the measurement of serum Igs: IgG, IgM, IgA, and IgE, which have age-dependent normal ranges (Table 33–3). Normal IgG, IgM, and IgA and increased IgE levels are indicative of atopy. Some patients may have normal Ig levels but fail to make protective antibodies to certain microbes; other patients have...
subnormal Ig levels but make protective antibodies. Specific antibodies include isoagglutinins, naturally occurring IgM antibodies that are detectable by age 6 months except in children with blood group AB. Specific IgG antibodies to protein antigens (tetanus, diphtheria, rubella, mumps) and polysaccharide antigens (Haemophilus influenzae, Streptococcus pneumoniae) can be measured after immunization. The response to polysaccharide antigens develops during the second year of life, but protein-conjugated vaccines elicit an earlier response in immunocompetent children. Assessing the antibody response to pneumococcal polysaccharide antigens can be helpful in the face of repeated pneumococcal infections. The gold standard is comparison of pre- and postimmunization titers.

Obtaining a CBC with differential and T- and B-lymphocyte counts are recommended if an initial screen reveals very low concentrations of all Ig classes. Certain types of hypogammaglobulinemia are characterized by low levels of or absent B lymphocytes, such as XL Bruton agammaglobulinemia. Protein electrophoresis can help identify monoclonal gammopathy as seen in XL lymphoproliferative syndrome, which can be complicated by fatal Epstein-Barr virus (EBV) infection, and in heavy-chain diseases. Serum albumin should be measured in patients with hypogammaglobulinemia to exclude secondary deficiencies due to protein loss through bowel or kidneys. IgG or IgA subclass measurements may be abnormal in patients with varied immunodeficiency syndromes, but they are rarely helpful in an initial evaluation.

### T Lymphocytes

The initial laboratory screening for a T-lymphocyte deficiency includes a CBC with cell differential to evaluate for a decreased absolute lymphocyte count (< 1000/μL) and enumeration of absolute numbers of T cells and their subsets, B cells, and natural killer (NK) cells (see Table 33–2). T-cell function can be analyzed by in vitro lymphocyte proliferation assays to mitogens that stimulate all T cells

</table>

and by specific antigens that stimulate only antigen-specific T cells. Borderline function must be interpreted based on clinical correlation. T-lymphocyte function is often also studied in vivo by delayed hypersensitivity skin tests to specific antigens, including Candida albicans, tetanus, or mumps, but a negative result is not helpful, as it may be due to young age, chronic illness, vitamin D deficiency, or poor test technique. T-lymphocyte deficiencies will often not manifest as skin-test anergy until the impairment is severe, for example as in AIDS. It is important to evaluate a patient’s specific antibody production because proper B-lymphocyte function and antibody production are dependent on adequate T-lymphocyte function. Therefore, most T-lymphocyte deficiencies manifest as combined T- and B-lymphocyte deficiencies.

Phagocyte Immunity

The initial laboratory screening for phagocyte disorders, mainly impaired neutrophil function, should include a CBC and cell differential to look for neutropenia. A blood smear can detect Howell-Jolly bodies in erythrocytes, indicative of asplenia, and abnormalities in lysosomal granules in neutrophils. An abnormality of the neutrophil respiratory burst, which would lead to impaired neutrophil bactericidal activity, can be tested by nitroblue tetrazolium (NBT) reduction. The dihydrorhodamine (DHR) flow cytometry assay assesses the same function more quantitatively. Leukocyte adhesion molecules can be studied by flow cytometry. Assays to study neutrophil phagocytosis of bacteria and phagocytic microbicidal activity are available in specialized laboratories.

The clinical symptom pattern that suggests a possible defect of phagocytic cell function should dictate which tests are used.

Complement Pathways (Figure 33–4)

Testing for total hemolytic complement activity with the CH50 assay screens for most of the diseases of the complement system. A normal CH50 titer depends on the ability of all 11 components of the classic pathway and membrane attack complex to interact and then lyse antibody-coated sheep erythrocytes. Alternative complement pathway deficiencies are identified by subnormal lysis of rabbit erythrocytes in the AH50 assay. For both assays the patient’s serum must be separated and frozen at −70°C within 30–60 minutes after collection to prevent loss of activity. Measuring levels of individual components is not necessary when both CH50 and AH50 are normal. If both the CH50 and AH50 are low, a deficiency in their shared terminal pathway (C3, C5, C6, C7, C8, or C9) would be the most common explanation. If the CH50 is low but the AH50 is normal, the deficiency must affect C1, C4, C2, or components of the lectin pathway. If the AH50 is low but the CH50 is normal, a deficiency in factors D or B or properdin should be suspected.

Pattern-Recognition Receptors

Selected laboratories offer tests to assess TLR function upon stimulation with ligands for different TLRs that have been identified. Mannose-binding lectin levels can be measured in
clinical laboratories. However, expression or function of pattern recognition receptors (PRRs) and associated gene mutations are studied mostly in a research setting at the current time.

**ANTIBODY DEFICIENCY SYNDROMES**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Recurrent bacterial infections, typically due to encapsulated pyogenic bacteria.
- Low immunoglobulin levels.
- Inability to make specific antibodies to vaccine antigens or infections.

**General Considerations**

Antibody deficiency syndromes include both congenital and acquired forms of hypogammaglobulinemia with low levels of one or more of the immunoglobulins IgM, IgG, and IgA. Deficiencies result in recurrent bacterial infections, typically with encapsulated bacteria, including pneumonia, otitis, sinusitis, meningitis, cellulitis, and sepsis. As a group, antibody deficiencies represent nearly half of all PIDs. They can be divided into (1) early defects of B-cell development, with absent B cells and severe hypogammaglobulinemia; (2) hyper-IgM syndromes with defects in Ig class switching; (3) common variable immunodeficiency (CVID), with insufficient antibody production; and (4) specific antibody deficiencies. Table 33–4 outlines primary antibody deficiency syndromes, laboratory findings, and genetic inheritance in these disorders.

1. **X-Linked Agammaglobulinemia**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Infections early in life, usually after age 4 months.
- Typical bacterial infections include infections with encapsulated bacteria, for example, *H influenzae*, *S pneumoniae*, *Staphylococcus aureus*, and *Pseudomonas aeruginosa*, but also *Mycoplasma* species.
- Risk for severe enteroviral infections and, rarely, polio due to live polio vaccine.
- Failure to thrive and absent lymphoid tissue on examination.
- Very low levels of Igs and B lymphocytes.

**General Considerations**

X-linked agammaglobulinemia (XLA) accounts for 85% of congenital hypogammaglobulinemia and occurs in about 1:200,000 male births. Children with XLA typically present with infections after 4 months of age, when maternally derived IgG levels have declined. XLA is caused by a gene mutation on the X chromosome (Xq21.33–q22) that affects the expression of a B-cell–specific tyrosine kinase (*BTK*), halting the maturation of B cells and resulting in low or absent B-cell numbers and serum Igs. Early detection and diagnosis of XLA allow Ig-replacement therapy to start before a potentially life-threatening infection can occur.

**Clinical Findings**

A. **Symptoms and Signs**

Sinopulmonary infections due to *H influenzae* and *S pneumoniae* are common, but deep tissue infections and arthritis due to *Mycoplasma* or *Ureaplasma* species can occur. Recurrent pulmonary infections may lead to bronchiectasis. Antibody-deficient patients are also at risk for polio due to oral polio vaccine strains, resulting in paralysis, and echoviruses causing chronic encephalitis. At presentation, male infants have scant or absent lymphoid tissue, including tonsils, adenoids, and lymph nodes. A small proportion also has a history of poor growth.

B. **Laboratory Findings**

Most patients have low levels of or absent Igs M, G, A, and E, and, despite a normal leukocyte count, few or no B lymphocytes. T-lymphocyte numbers and function are normal. Genetic testing for a *BTK* gene mutation confirms the diagnosis in affected males. Female carriers can be detected by genetic testing or screening for *BTK* protein expression in platelets followed by mutation analysis if needed.

**Differential Diagnosis**

The differential diagnosis includes other causes of antibody deficiency and combined immunodeficiencies (see Table 33–4; Table 33–5). Additional causes of recurrent infections and low Ig levels include protein loss through renal or gastrointestinal disease, but patients with these disorders present with normal numbers of B lymphocytes and, typically, an isolated IgG deficiency.

**Treatment**

Current therapy consists of lifelong Ig-replacement therapy. In addition to preventing infections, Ig replacement usually results in resolution of inflammatory arthritis and improves growth. Because the severity of infections varies and antibiotics are widely used, the diagnosis is often delayed for years, but XLA should be considered in males with recurrent

infections regardless of severity. Early diagnosis can prevent permanent disability and premature death.

2. Autosomal Recessive Congenital Agammaglobulinemia

- **General Considerations**
  
  Autosomal recessive congenital agammaglobulinemia is rare, accounting for less than 15% of all congenital hypogammaglobulinemia, and occurs in both male and female children. In the most common form, it is caused by mutations of the IgM heavy-chain gene on chromosome 14q32. These mutations result in abnormal or absent IgM expression and abnormal development of B cells with decreased or absent antibody production.

- **Clinical Findings**

  - **A. Symptoms and Signs**
    
    Similarly to patients with XLA, children present with recurrent and severe bacterial infections, typically before age 6 months. Infections include pneumonia, otitis, sinusitis, meningitis, cellulitis, and sepsis. Chronic central nervous system (CNS) infections by enteroviruses have been observed.

- **B. Laboratory Findings**

  Patients usually have low numbers of circulating B lymphocytes and low levels of or absent immunoglobulins. Specific antibody function is poor. When the diagnosis is suspected, the detection of a mutation in the \( \mu \) heavy chain can confirm the most common type. Additional mutations include mutations of the genes encoding the Ig\( \alpha \) and Ig\( \beta \) molecules, the \( \lambda 5 \) surrogate light chain, BLNK or LRRC8 genes.

- **Differential Diagnosis**

  The differential diagnosis is similar to that of XLA and includes XLA for male patients.

- **Treatment**

  Treatment and prognosis are similar to those outlined for XLA.

3. Hyper-IgM Syndromes

Hyper-IgM (HIGM) syndromes are a heterogeneous group of genetic disorders (see Table 33–4) with impaired Ig class switching from IgM to production of IgG, IgA, or IgE associated with normal or elevated serum IgM. If signaling through CD40 is affected, patients present also with
opportunistic bacterial infections. Deficiencies of AID or UNG differ from CD40L and CD40 deficiencies in that the patients have large lymph nodes with germinal centers and are not susceptible to opportunistic infections. Patients with HIGM syndrome are at increased risk of autoimmune diseases. Treatment with Ig replacement decreases infections and often normalizes IgM levels. XL CD40L deficiency and NFkB signaling defects will be addressed further in section Other Combined Immunodeficiency Disorders.

4. Common Variable Immunodeficiency

General Considerations

Common variable immunodeficiency (CVID) is a diagnosis of exclusion after other causes of hypogammaglobulinemia have been eliminated. The onset may be at any age, and the incidence approaches 1:30,000. Many cases are sporadic, but a small percentage of patients have autosomal dominant or recessive inheritance, and some cases are associated with specific HLA-DR/DQ alleles (see Table 33–4).

Clinical Findings

A. Symptoms and Signs

Patients have recurrent infections, most often of the sinonasal tract, but chronic gastrointestinal infections may manifest with recurrent diarrhea. Patients with CVID are at risk for developing bronchiectasis, autoimmune diseases (idiopathic thrombocytopenic purpura, autoimmune hemolytic anemia, rheumatoid arthritis, and inflammatory bowel disease), and malignancies (especially gastric carcinoma and lymphoma).

B. Laboratory Findings

Laboratory findings are variable, but typically reveal low levels of IgG and IgA, normal numbers of B lymphocytes, low numbers of memory B lymphocytes (evaluated by flow cytometry), and abnormal specific antibody levels and responses. Some patients have evidence of T-lymphocyte abnormalities as well. Chronic gastrointestinal tract infections are often due to G lamblia or C jejuni.

Although CVID is typically a diagnosis of exclusion, recent research has revealed multiple specific genetic mutations in patients with CVID. One example is a mutation in a member of the tumor necrosis factor receptor family, identified as transmembrane activator and calcium-modulator and cyclophilin ligand interactor (TACI), which mediates isotype switching in B lymphocytes. TACI mutations were recently found in 10%–15% of patients with CVID, as well as in some relatives of CVID patients with IgA deficiency. The mutations appear to be autosomal dominant, with variable penetrance of clinical immunodeficiency and autoimmune disease, and impairment of T-regulatory cell function.

Differential Diagnosis

When a patient presents with recurrent infections, low immunoglobulin levels, and potentially autoimmune symptoms, many different diagnoses must be considered, including other causes of low immunoglobulin levels (loss and abnormal production) and autoimmune diseases. CVID patients have normal numbers of B lymphocytes despite their poor specific antibody responses, which differentiates them from patients with XLA and AR agammaglobulinemia. Patients with CVID also lack the specific mutations responsible for those other disorders. However, CVID patients often have decreased numbers of memory B cells (IgM−/IgD−/CD27+/CD20+ B cells).

Treatment

Treatment includes lifelong Ig-replacement therapy and routine assessment for bronchiectasis, autoimmune disorders, and malignancies. The prognosis can be good and depends on the time to diagnosis and implementation of Ig-replacement therapy. Other complications include B-cell hyperplasia in the gut that may be severe enough to resemble Crohn disease, and gastric atrophy with achlorhydria, sometimes followed by pernicious anemia. Lymphoreticular proliferation can occur after EBV infection and is not always malignant.

5. Acquired Hypogammaglobulinemia

Acquired forms of hypogammaglobulinemia are common and may develop at any age. Causes of secondary hypogammaglobulinemia (nephrotic syndrome and protein-losing enteropathy) should be excluded by measuring serum albumin. The loss of albumin (MW 69323 Da) is usually paralleled by a loss of IgG (MW 150000 Da). Generally, acquired forms are not treated with Ig-replacement therapy because, although immunoglobulin levels are low, antibody function is adequately protective. Morphologic disorders or associated syndromes may point to a specific diagnosis.

6. Transient Hypogammaglobulinemia

Serum IgG levels normally decrease during an infant’s first 4–6 months of life as maternal IgG transmitted in utero is metabolized. Transient hypogammaglobulinemia represents a delay in the onset of immunoglobulin synthesis that results in a prolonged nadir. Symptomatic patients present with recurrent infections, including upper respiratory tract infections, otitis, and sinusitis. The diagnosis is suspected in infants and young children with low levels of IgG and IgA (usually two standard deviations below normal for age), but normal levels of IgM and normal numbers of circulating B lymphocytes. Most affected children have normal specific antibody responses and T-lymphocyte function. Apart from appropriate antibiotics,
no treatment is required. Infants with severe infections and hypogammaglobulinemia could be given Ig replacement, but benefits and risk must be considered and this is rarely necessary. Recovery occurs between 18 and 30 months of age, and the prognosis for affected children is excellent provided infections are treated promptly and appropriately.

7. Selective Immunoglobulin Deficiencies

Selective IgA deficiency is the most common immune abnormality, found in approximately 1:700 persons. It is defined by a serum IgA level less than 7 mg/dL. Serum IgM, IgG, specific antibodies, and B- and T-lymphocyte numbers and function are normal. IgA is primarily effective in its secreted form on mucosal surfaces. Therefore, symptomatic patients with low serum IgA develop upper respiratory tract infections, diarrhea, or both, but most people are asymptomatic.

Associations also exist with inflammatory bowel disease, allergic disease, asthma, and autoimmune disorders (thyroiditis, arthritis, vitiligo, thrombocytopenia, and diabetes). IgA replacement is currently not feasible. For the majority of symptomatic IgA-deficient patients, antibiotics and appropriate autoimmune therapies are sufficient. Caution must be exercised, as IgA-deficient patients are at risk for developing anti-IgA antibodies with blood product exposure, and the administration of blood products can result in anaphylaxis. Therefore, when blood products are needed, washed packed red blood cells and volume expanders without blood products are recommended.

The possibility that deficiency of an IgG subclass (eg, abnormally low serum IgG₂, IgG₃, or IgG₄) might predispose to recurrent upper respiratory tract infections in patients with normal total serum immunoglobulin levels is not well established. Normally, IgG₃ comprises over 60% of total IgG, IgG₂ over 10%, IgG₁ about 5%, and IgG₄ may be undetectable in up to 20% of healthy persons. Additionally, serum levels are age related. It has been difficult to establish a link between IgG subclass deficiencies and any consistent pattern of infections. IgG replacement should be reserved for patients with defects in specific antibody production and recurrent infections, which is rarely seen in patients with selective IgA or IgG subclass deficiencies.

Treatment of Hypogammaglobulinemia

The mainstay of therapy for hypogammaglobulinemia is replacement with IgG, but appropriate management of infections is also important. Curative therapy with bone marrow transplantation (BMT) has been successful in patients with XL HIGM syndrome. Replacement IgG is usually given by intravenous infusions at a dose of 400–600 mg/kg every 3–4 weeks to maintain trough serum IgG levels above 500–800 mg/dL (a higher trough level is targeted for patients with established pulmonary disease). Subcutaneous replacement is available, but it requires more frequent injections and may limit maximum dosing. The aim of treatment is to prevent future infections and minimize any progression of chronic lung disease (bronchitis or bronchiectasis). Despite the passive immunity provided by replacement IgG, infections remain a persistent risk for affected patients. The prognosis also depends on timely and appropriate antibiotic therapy. Typical infecting organisms include encapsulated bacteria, but Ureaplasma and Mycoplasma species must also be considered. Infusions are generally well tolerated, with most reactions being mild, including headache, back and limb pain, anxiety, and chest tightness. Rare systemic reactions can occur, including tachycardia, shivering, fever, and, in severe cases, anaphylactoid shock. These adverse symptoms can be prevented by pretreatment with corticosteroids, antihistamines, and nonsteroidal anti-inflammatory drugs. For patients with congenital hypogammaglobulinemia, replacement therapy is currently lifelong. As a precautionary measure, patients with agammaglobulinemia or hypogammaglobulinemia should not receive live vaccines, but nonlive vaccines may be beneficial, particularly in patients with CVID.

SEVERE COMBINED IMMUNODEFICIENCY DISEASES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Onset in first year of life.
- Recurrent infections caused by bacteria, viruses, fungi, and opportunistic pathogens.
- Chronic diarrhea and failure to thrive.
- Absent lymphoid tissue.

General Considerations

Severe combined immunodeficiency diseases (SCIDs) encompass congenital diseases caused by different genetic mutations that result in severe deficiency of T and B lymphocytes. Despite differences in underlying mutations, affected patients present similarly, with recurrent infections caused by bacteria, viruses, fungi, and opportunistic pathogens. Patients often suffer from chronic diarrhea and failure to thrive, and typically die within the first year of life without treatment. Children with atypical SCID usually survive longer due to mutations in SCID-associated genes with residual protein function. SCID must be considered in the differential diagnosis in any infant with diarrhea and hypogammaglobulinemia.

Clinical Findings

A. Symptoms and Signs

Common presentations include persistent cough, tachypnea, or hypoxia secondary to underlying Pneumocystis carinii...
infection, or persistent oral or diaper candidiasis. Physical examination is notable for a lack of lymphoid tissue including tonsils and lymph nodes. A chest radiograph usually demonstrates an absent thymic shadow.

**B. Laboratory Findings**

Laboratory evaluation often reveals lymphopenia and some degree of hypogammaglobulinemia. Occasionally, an infant with SCID will present with normal numbers of lymphocytes resulting from transfusion-related engraftment or maternal T-lymphocyte engraftment via peripartum transfusion. NK cells and B-lymphocyte numbers may be decreased, normal, or elevated. Numbers of CD31+/CD45RA+/CD4+ recent thymic emigrant T cells reflect thymic T-cell output and are usually decreased in SCID patients. Additionally, in vitro lymphocyte assays show poor response to mitogens, and specific antibodies are absent. Antenatal diagnosis is possible. Once the diagnosis of SCID is suspected, genetic testing should be pursued to confirm the diagnosis and the mutation present for both prognostic and genetic counseling purposes. Clinical presentation and treatment are generally similar. The variants of SCID can be organized by the presence or absence of specific lymphocytes, including T, B, and NK cells (see Table 33–5).

**Differential Diagnosis**

The differential diagnosis of SCID includes other causes of recurrent and severe infections and abnormal immune responses, most notably HIV disease. Other causes of hypogammaglobulinemia or agammaglobulinemia may be considered but can usually be ruled out in the presence of abnormal T-lymphocyte numbers and function. The infection spectrum and severity of presentation in children with SCID is more severe and of earlier onset than that seen with agammaglobulinemia. Symptoms of congenital abnormalities with combined immunodeficiency features are discussed later in this chapter (see section on Genetic Syndromes Associated With Immunodeficiency).

**Treatment**

When SCID is suspected, *Pneumocystis* prophylaxis with trimethoprim–sulfamethoxazole and replacement Ig therapy should be initiated. **Patients with suspected SCID should only be transfused with irradiated blood products and should not receive any live vaccines.** Confirmation of the diagnosis should include screening for SCID subtypes listed in Table 31–5. BMT offers the best possibility of cure, with use of a human leukocyte antigen (HLA)–matched sibling offering the highest chance of success. In affected patients without HLA-identical donors, HLA haploidentical bone marrow cells from family members or HLA-matched unrelated donors are used. For most patients, myeloablation is not necessary as the patient is without T lymphocytes. Additionally, most patients do not require prophylaxis for graft-versus-host disease (GVHD) unless the donor is unrelated. T-lymphocyte reconstitution takes approximately 4 months, but only about 50% of patients regain full B-lymphocyte function, with the majority requiring long-term Ig replacement. For months post transplantation, patients are susceptible to many serious infections, and prophylaxis is usually continued. Additionally, any signs or symptoms of infection must be promptly investigated and aggressively treated. The highest rate of success is in the youngest patients prior to developing infections (> 95% survival), but overall rates of survival range from 50% to 100% depending on the underlying mutation. XL SCID and ADA deficiency have been treated with gene therapy. Normal gene function was transduced in XL SCID patients, but owing to insertion of the retroviral vector near an oncogene, some patients developed lymphoproliferative disorders. At this time, safer vectors are being sought.

1. **X-Linked Severe Combined Immunodeficiency**

XL SCID, the most common form (40%) of SCID, results from mutations in *IL2RG* (IL-2 receptor gene) that encodes the common γ chain. The γ-chain protein is shared by multiple cell surface receptors for cytokines that are essential for T-lymphocyte maturation, including IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21. Within the first 3 months of life, male infants present with diarrhea, cough, and rash. Laboratory evaluation reveals low T-lymphocyte numbers, normal numbers of B lymphocytes (which do not produce functional antibody), and absent NK cells.

2. **Adenosine Deaminase Deficiency**

Adenosine deaminase deficiency (ADA) is an AR form of SCID caused by absence of adenosine deaminase, which is important for removal of toxic metabolites formed in lymphocytes, including adenosine, 2′-deoxyadenosine, and 2′O-methyladenosine. Increased levels of these metabolites result in lymphocyte death. Subsequently, affected patients develop complete absence of T-lymphocyte function and progressive decrease in immunoglobulin production. ADA SCID is distinguished from other variants of SCID by the following findings: the most profound lymphopenia (< 500/mm3); skeletal abnormalities, including chondro-osseous dysplasia (flared costochondral junctions and bone-in-bone anomalies in vertebrae); and deficiency of all types of lymphocytes. Diagnosis is suspected in patients with profound lymphopenia and recurrent infections. The diagnosis is confirmed with a red blood cell assay for ADA activity. The genetic mutation is on chromosome 20q13.2–13.11. In addition to BMT, restoration of immune competence can occur in
some patients with weekly infusions of polyethylene glycol–stabilized ADA enzyme conjugate. Gene therapy of stem cells with an ADA-incorporating retroviral vector has been successful, but the vector caused oncogenic adverse effects.

3. Janus Kinase 3 Deficiency
Another form of AR SCID is due to mutations in the gene encoding janus kinase 3, which is important for intracellular signaling through the common γ chain. The clinical presentation and lymphocyte phenotype most closely resemble XL SCID, with low T and NK lymphocytes, and normal or elevated, nonfunctional B lymphocytes.

4. Interleukin-7-Receptor-α-Chain Deficiency
IL-7-receptor-α-chain (IL-7Rα) deficiency SCID is transmitted by AR inheritance. The IL-7 receptor is important for T-lymphocyte maturation and mutations result in low T-lymphocyte numbers, but normal numbers of dysfunctional B lymphocytes and NK cells.

5. Recombinase-Activating Gene Deficiencies
Another form of AR SCID is due to mutations in recombinase-activating genes (RAG1 and RAG2), which encode proteins critical for assembling antigen receptor genes for both T and B lymphocytes. Several mutations in these genes have been described. The clinical presentation is similar to that of other forms of SCID, but the lymphocyte phenotype differs, as patients with SCID due to RAG1 or RAG2 mutations lack both T and B lymphocytes but maintain normal or elevated numbers of NK cells.

Omenn syndrome is an autosomal AR syndrome characterized by SCID, eczematoid rash, hepatosplenomegaly, lymphadenopathy, and alopecia. The disease is caused by mutations in RAG1, RAG2, or Artemis mutations (see as follows). Laboratory evaluation reveals absent B lymphocytes, normal to elevated T-lymphocyte numbers with restricted function, and normal functional NK cells. Additionally, affected patients often have eosinophilia and elevated levels of IgE. The syndrome is typically fatal, although BMT has been used successfully.

6. CD3-δ-Chain Deficiency
CD3-δ-chain (CD3δ) deficiency is a rare form of AR SCID. Homozygous defects in the CD3δ chain halt T-lymphocyte maturation. Clinical presentation and lymphocyte phenotype are similar to IL-7Rα deficiency, but CD3δ-chain deficiency differs from other forms of SCID in that these patients have a normal-appearing thymic silhouette on chest radiograph.

7. CD45 Deficiency
Another rare form of AR SCID is due to mutations in the gene for CD45. CD45 is a tyrosine phosphatase important for regulating signal transduction. Affected patients have a similar presentation to other forms of SCID and a lymphocyte phenotype with low to absent T and NK cells, but normal B lymphocytes.

8. Artemis Deficiency
Artemis is a DNA repair factor important for repairing cuts in the double-stranded DNA essential for the assembly of antigen receptors for T and B lymphocytes. Inheritance is AR, and clinical presentation and lymphocyte phenotype are similar to those seen in RAG1 and RAG2 deficiencies.

9. ZAP-70 Deficiency
Deficiency of ζ-chain–associated protein (ZAP)-70 results in a rare form of AR SCID. ZAP-70 is a tyrosine kinase critical for T-lymphocyte signaling and activation. Clinical presentation is similar to that of other forms of SCID, but most affected patients have palpable lymph nodes and visible thymic silhouette. Lymphocyte evaluation reveals absence of CD8+ T lymphocytes, normal but nonfunctional CD4+ T lymphocytes, normal numbers of poorly functioning B lymphocytes, and normal numbers and function of NK cells.

OTHER COMBINED IMMUNODEFICIENCY DISORDERS
Combined immunodeficiencies include defects that directly impair both T and B lymphocytes, as well as T-lymphocyte–specific defects, because proper B-lymphocyte function and antibody production are dependent on T-lymphocyte help. Therefore, most T-lymphocyte deficiencies manifest as combined impairments.

1. Wiskott-Aldrich Syndrome
- Immunodeficiency with recurrent infections.
- Microplatelet thrombocytopenia.
- Eczema.
- Occurs only in males.
General Considerations

Wiskott-Aldrich syndrome (WAS) is an XL recessive disease characterized by immunodeficiency, microplatelet thrombocytopenia, and eczema. The syndrome results from mutations of the gene encoding WAS protein (WASP) at X11p. WASP is a protein involved in the rearrangement of actin and is important in interactions between T lymphocytes and antigen-presenting cells.

Clinical Findings

A. Symptoms and Signs

Common presenting symptoms include mucosal bleeding, bloody diarrhea, cerebral hemorrhage, and severe infections with polysaccharide-encapsulated bacteria, but the clinical presentation can vary from classic severe WAS to mild thrombocytopenia without immunodeficiency, or X-linked thrombocytopenia (XLT), depending on the mutation. Early deaths are due to bleeding and infections, but malignancies and autoimmune syndromes can develop over time. Survival beyond adolescence is rare in patients not receiving treatment, although XLT is sometimes diagnosed in adults.

B. Laboratory Findings

Laboratory findings that suggest the diagnosis are a low platelet count, small platelets, low or absent isohemagglutinins, and reduced antibody responses to polysaccharide antigens (S pneumoniae and H influenzae). IgM may be low; IgG is usually normal; and IgA and IgE are often high. The diagnosis can be confirmed by genetic testing for a mutation of the WASP gene or by assessing WASP expression. Genetic testing can also be used for carrier screening.

Differential Diagnosis

In addition to WAS and XLT, the differential diagnosis in a patient with a low platelet count must include other causes of platelet consumption, destruction, and abnormal production, such as idiopathic thrombocytopenic purpura, leukemia or myelodysplasia, drug adverse effect, and infection. WAS can be differentiated from these other conditions by small-sized platelets on smear evaluation, the presence of eczema and other atopic features, and documented immune dysfunction. Additionally, there is a continuous spectrum between WAS and XLT that lacks immunodeficiency. Subsequently, a scoring system has been developed to help clinicians distinguish WAS from XLT.

Treatment

Treatment includes infection prophylaxis with antibiotics (including trimethoprim-sulfamethoxazole for P carinii pneumonia) and IVIG-replacement therapy for patients with deficient antibody responses. Splenectomy to reduce thrombocytopenia has been helpful in some patients with XLT, but it must be followed by antibiotic prophylaxis because of the increased risk of septicemia and sudden death. Platelet transfusions should be avoided unless severe bleeding has occurred. Finally, BMT using the best-matched donor offers the possibility of a definitive cure, but it is associated with morbidity and mortality.

2. 22q11.2 Deletion Syndrome (DiGeorge Syndrome)

General Considerations

DiGeorge syndrome or 22q11.2 deletion syndrome is an AD syndrome, resulting in defective development of the third and fourth pharyngeal pouches. There is considerable variability in phenotype based on the location and extent of the deletion, but deletions that include the TBX1 gene appear relevant. Overlapping syndromes include velocardiofacial syndrome and Shprintzen syndrome. The incidence is about 1:4000 births, and the abnormal chromosome is usually inherited from the mother. The associated immunodeficiency is secondary to the aplastic or hypoplastic thymus, where T-lymphocyte maturation occurs. Surprisingly, most patients have no or only mild immune defects. The term partial DiGeorge syndrome is commonly applied to these patients with impaired rather than absent thymic function.

Clinical Findings

A. Symptoms and Signs

Clinical characteristics include congenital heart defects, hypocalcemia due to hypoparathyroidism, distinctive craniofacial features, renal anomalies, and thymic hypoplasia. The term partial DiGeorge syndrome is commonly applied to these patients with impaired rather than absent thymic function.
Patients have an increased risk to develop schizophrenia and autoimmune disorders.

B. Laboratory Findings

Laboratory evaluation typically reveals normal to decreased numbers of T lymphocytes with preserved T-lymphocyte function and normal B-lymphocyte function. In the rare patient with absent or dysfunctional T lymphocytes, B-lymphocyte function and antibody production may be abnormal. Over time, T-lymphocyte numbers normalize in the majority of patients who have low numbers of T lymphocytes at initial presentation. The diagnosis is confirmed via fluorescence in situ hybridization (FISH) chromosomal analysis for the microdeletion on chromosome 22, or microarray-based comparative genomic hybridization.

Treatment

Treatment of the 22q11.2 deletion syndrome may require surgery for cardiac defects, and vitamin D, calcium, or parathyroid hormone replacement to correct hypocalcemia and treat seizures. Transfusion products should be irradiated. Both thymic grafts and BMT have been used successfully in patients with absent T-lymphocyte immunity. Prior to giving live vaccines, T-cell numbers and function should be assessed if not done earlier, to prevent vaccine-related side effects.

3. Ataxia-Telangiectasia

Ataxia-telangiectasia (A-T) is a rare, neurodegenerative, AR-inherited disorder caused by mutations in the ataxia-telangiectasia–mutated (ATM) gene located on chromosome 11q22–23 that encodes the ATM protein, a protein kinase involved in repair of double-stranded DNA and cell cycle regulation. A-T is characterized by progressive cerebellar ataxia, telangiectasia, and variable immunodeficiency. Children usually present as toddlers with slurred speech and balance problems, and also with sinopulmonary infections. Telangiectasias of the conjunctivae and exposed areas (eg, nose, ears, and shoulders) follow later during childhood. Respiratory tract infections promoted by respiratory muscle weakness, swallowing dysfunction and recurrent aspirations, and malignancies, including carcinomas and lymphomas, are the major causes of death between the second and fourth decade of life. Abnormal findings in A-T include elevated α-fetoprotein levels that increase over time and are used diagnostically; immunoglobulin deficiencies, including low levels of IgA, IgE, or IgG; and defective ability to repair radiation-induced DNA fragmentation. There is no definitive treatment, although Ig replacement and aggressive antibiotics have been used with limited success. Heterozygotes have an increased risk for breast cancer.

Similarly to A-T, the Nijmegen breakage syndrome is a disorder associated with impaired DNA repair and mutations in the NBS1 gene that shows more severe clinical features, including microcephaly and facial dysmorphisms, small stature, immunodeficiency, and increased risk for lymphoid malignancies.

4. X-Linked Hyper-IgM Syndrome

X-linked hyper-IgM (HIGM) syndrome or CD40L deficiency is the most common and most severe form of HIGM syndrome and involves a mutation in the gene encoding for CD40L (CD154). CD40L is expressed on activated T lymphocytes and necessary for T cells to induce immunoglobulin isotype switching in B cells. Unlike the AR forms of HIGM syndrome, the mutation results in both antibody- and cell-mediated deficiencies, as the interaction between CD40L on T cells and CD40 on B cells and antigen-presenting cells is important for both antibody production and T-cell activation. Affected males have normal numbers of B lymphocytes, low levels of IgG and IgA, but normal or elevated levels of IgM. Typically, male infants present with recurrent bacterial and opportunistic infections such as P carinii pneumonia or Cryptosporidium diarrhea. Additionally, affected males have a high frequency of sclerosing cholangitis, increased liver and biliary tract carcinomas, neutropenia, and autoimmune syndromes, including thrombocytopenia, arthritis, and inflammatory bowel disease. Conservative treatment includes Ig replacement and antibiotic prophylaxis. Because the prognosis is still quite poor, BMT has been used with initial success.

5. NF-κB Signaling defects

Immunodeficiency due to mutations in the gene for nuclear factor-κB (NF-κB)—essential modulator (NEMO; IKBKG gene) is an XL syndrome in which male patients manifest ectodermal dysplasia (abnormal, conical teeth, fine sparse hair, and abnormal or absent sweat glands) and defects of T and B lymphocytes. NF-κB is involved in signaling through CD40 on B cells, and NEMO mutations result in abnormal immunoreceptor signaling. Many mutations are fatal in utero for male infants. Female carriers may have incontinence pigmented. Surviving males present with early serious infections, including opportunistic infections with P carinii and atypical mycobacteria. Laboratory evaluation reveals hypogammaglobulinemia that may present as HIGM syndrome and poor specific antibody production, but normal numbers of T and B lymphocytes. Functional evaluation of lymphocytes demonstrates variable response. Because patients with confirmed NEMO mutations are quite rare, the best treatment course is unknown, but aggressive antibiotic therapy in combination with Ig replacement as well as BMT has been used. The prognosis is dependent on the severity of immunodeficiency, with most deaths due to infection. Mutations in the NF-κB1A gene that encodes 1kBx (nuclear factor of kappa light
polypeptide gene enhancer in B-cell inhibitor alpha) result in an AD-inherited defect with similar clinical presentation.

6. Combined Immunodeficiency With Defective Expression of MHC I & II

Major histocompatibility complex class I (MHC I) deficiency or bare lymphocyte syndrome type I is an AR-combined immunodeficiency. Affected patients have abnormal expression of the transporter associated with antigen processing (TAP). TAP proteins are important for intracellular transport and expression of MHC I on cell surfaces. Patients with bare lymphocyte syndrome type I present with recurrent sinopulmonary and skin infections. The diagnosis is confirmed by demonstrating an absence of MHC I expression.

Major histocompatibility complex class II (MHC II) deficiency or bare lymphocyte syndrome type II is a rare AR-combined immunodeficiency in which cells lack MHC II expression due to mutations in CIITA, RFX-5, RXAP, or RFZANK genes. Clinical presentation includes recurrent viral, bacterial, and fungal infections. Patients with bare lymphocyte syndrome type II have normal numbers of T and B lymphocytes, but low CD4+ lymphocyte numbers, abnormal lymphocyte function, and hypogammaglobulinemia. They also have a high incidence of sclerosing cholangitis. When this diagnosis is suspected, demonstration of absent MHC II molecules confirms the disorder. Severe cases are fatal without BMT, but milder phenotypes may be managed with Ig replacement and aggressive use of antibiotics.

7. Purine Nucleoside Phosphorylase Deficiency

Purine nucleoside phosphorylase (PNP) deficiency is an immunodeficiency due to defects in the gene encoding PNP, which is important in the purine salvage pathway. Deficiency of PNP causes toxic metabolites that result in T-lymphocyte death, but in many patients B lymphocytes are spared. Not only does this AR disease result in recurrent and serious infections, but affected patients also have concomitant neurologic (developmental delay, ataxia, and spasticity) and autoimmune disorders. Infections present at variable ages. Laboratory evaluation reveals low numbers of or absent T lymphocytes and a variable B-lymphocyte deficiency. Without BMT, this disease is fatal due to infection or malignancy.

PHAGOCYTE DISORDERS

Phagocyte defects include abnormalities of both numbers (neutropenia) and function of polymorphonuclear neutrophils. Functional defects consist of impairments in adhesion, chemotaxis, bacterial killing, or, less often, of combinations of these.

1. Neutropenia

The presence of neutropenia should be considered when evaluating recurrent infections. The diagnosis and treatment of neutropenia is discussed in Chapter 30. Additionally, some PID syndromes are associated with neutropenia (e.g., XLA).

2. Chronic Granulomatous Disease

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Recurrent infections with catalase-positive bacteria and fungi.
- XL and AR forms.
- Caused by abnormal phagocytosis-associated generation of microbicidal oxygen metabolites (respiratory burst) by neutrophils, monocytes, and macrophages.

General Considerations

Chronic granulomatous disease (CGD) is caused by a defect in any of several genes encoding proteins in the enzyme complex nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, which results in defective superoxide and hydrogen peroxide generation during ingestion of microbes. Most cases (probably 75%) are inherited as an XL recessive trait; the rest are AR in inheritance.

Clinical Findings

A. Symptoms and Signs

The typical clinical presentation is characterized by recurrent abscess formation in subcutaneous tissue, lymph nodes, lungs, and liver, and by pneumonia and eczematous and purulent skin rashes. Infecting organisms are typically catalase-positive bacteria, which can break down their own hydrogen peroxide and thus avoid death when captured in a CGD phagocytic vacuole. (Streptococci, pneumococci, and H influenzae lack catalase and are not unusually pathogenic in CGD.) Aspergillosis is also common and a frequent cause of death. Lymphadenopathy and hepatosplenomegaly are found on physical examination, and granulomas are seen in histopathologic sections. Granulomatous inflammation can narrow the outlet of the stomach or bladder in these patients, leading to vomiting or urinary obstruction.

B. Laboratory Findings

Patients typically present with serious infection, positive microbial cultures, and neutrophilia. The most common infecting organisms are S aureus, Aspergillus species,
Burkholderia cepacia, and Serratia marcescens. (Culture of either of the last two should suggest this diagnosis.) Patients also present with granulomas of lymph nodes, skin, liver, and genitourinary tract. The erythrocyte sedimentation rate may be elevated without obvious infection. The diagnosis is confirmed by demonstrating lack of hydrogen peroxide production using the DHR flow cytometry assay or lack of superoxide production using the NBT test. Both tests can demonstrate carrier status of XL disease.

Differential Diagnosis

The differential diagnosis includes other phagocyte abnormalities or deficiencies described in this section, as well as the rare neutrophil granule deficiency. Other immunodeficient states leading to severe bacterial or fungal infections should be considered, but none have the striking abscess formation and deficient phagocytosis-associated respiratory burst that characterize CGD.

Treatment

Daily intake of an antimicrobial agent such as trimethoprim-sulfamethoxazole is indicated in all patients; an oral antifungal agent like itraconazole and regular subcutaneous injections of interferon-γ can greatly reduce the risk of severe infections. BMT has been successful in some cases, but the risk of death is high unless the patient’s condition is stable. Gastric or GU obstruction can be relieved by short-term steroid therapy.

3. Leukocyte Adhesion Defects Types I & II

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Recurrent serious infections.
- “Cold” abscesses without pus formation.
- Poor wound healing.
- Gingival or periodontal disease (or both).

General Considerations

The ability of phagocytic cells to enter peripheral sites of infection is critical for effective host defense. In leukocyte adhesion defect (LAD), defects in proteins required for leukocyte adherence to and migration through blood vessel walls prevent these cells from arriving at the sites of infection. LAD I is an AR disease caused by mutations in the common chain of the β₂ integrin family (CD18) located on chromosome 21q22.3. These mutations result in impaired neutrophil migration, adherence, and antibody-dependent phagocytosis. LAD II is a rare AR disease caused by an inborn error in fucose metabolism that results in abnormal expression of leukocyte Sialyl-Lewis X (CD15s), which binds to selectins on the vessel endothelium. The resulting phenotype is similar to LAD I, with recurrent infections, lack of pus formation, poor wound healing, and periodontal disease. LAD II patients also have developmental delays, short stature, dysmorphic facies, and the Bombay (hh) blood group.

Clinical Findings

A. Symptoms and Signs

Patients present with variably severe phenotypes, including recurrent serious infections, lack of pus formation, poor wound healing, and gingival and periodontal disease. The hallmark is little inflammation and absent neutrophils on histopathologic evaluation of infected sites (ie, “cold” abscesses), especially when concurrent with neutrophilia, an expression of poor adherence to vessel walls. The most severe phenotype manifests with infections in the neonatal period, including delayed separation of the umbilical cord with associated omphalitis.

B. Laboratory Findings

Laboratory evaluation often demonstrates a striking neutrophilia. Diagnosis of suspected cases is confirmed by flow cytometry analysis for CD18 (LAD I) or CD15s (LAD II).

Treatment

Treatment includes aggressive antibiotic therapy. Fucose supplementation in LAD II has been reported with some success.

4. Glucose-6-Phosphate Dehydrogenase Deficiency

Rare forms of XL glucose-6-phosphate dehydrogenase deficiency with associated hemolytic anemia affect leukocytes as well as erythrocytes and result in recurrent infections due to an abnormal neutrophil respiratory burst, probably due to NAD/NADPH deficiency.

5. Myeloperoxidase Deficiency

Leukocyte myeloperoxidase (MPO) is important for intracellular destruction of C albicans. Although deficiency is quite common, only a very few patients with concurrent diabetes have had severe candidal infections. Diagnosis can be confirmed with assays measuring MPO levels in leukocytes.

COMPLEMENT DEFICIENCIES

Complement contributes to innate immunity and facilitates antibody-mediated immunity through opsonization, lysis of target cells, and recruitment of phagocytic cells. The complement system includes three interactive pathways
of enzymatic reactions: classic, alternative, and lectin (see Figure 33–4). All three pathways generate cleavage of C3 and result in promotion of inflammation, elimination of pathogens, and enhancement of the immune response. Activation of the complement system occurs through microbial products, tissue enzymes, and surface-bound IgG and IgM antibodies or pentraxins, for example C-reactive protein.

1. Complement Component Deficiencies

Deficiencies of individual complement components (C1–C9) are inherited as autosomal codominant traits, each parent contributing one null gene. Serum levels of the deficient component are about half normal in the parents and zero or almost zero in the patients. Deficiencies of C1, C2, or C4 predispose to increased infections but are particularly associated with autoimmune disorders such as systemic lupus erythematosus. Patients with homozygous C2 deficiency can present at any age in childhood with bacteremia or meningitis due to *S pneumoniae* or *H influenzae*. Primary C3 deficiency presents with severe pyogenic infections since C3 is critical for opsonization in both the classic and alternative pathways. Deficiency of the control protein factor I, which acts to break up the C3-cleaving complex formed in the classic or alternative pathway, leads to unbridled consumption of C3 and, thereby, severe bacterial infections. Deficiency of a terminal complement component in the membrane attack complex (C5, C6, C7, C8, and C9) or of properdin (an XL alternative pathway control protein) results in recurrent neisserial meningitis or disseminated gonococcal infection. Survivors of either of these serious neisserial infections should be screened for complement deficiency, first with a CH50 assay and later with an AH50 assay if the CH50 is normal.

Mannose-binding lectin and ficolins-1, 2, and 3 serve as the recognition components of the lectin pathway, which recognizes microbial surface carbohydrates. Deficiency of MBL has been linked to increased risk of infections in infancy and in patients who have another defect of host defense. Ficolin-3 deficiency has been associated with severe infections.

2. Hereditary Angioedema Due to C1 Inhibitor Deficiency

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Recurrent episodes of angioedema often triggered by trauma.
- No associated urticaria or pruritus.
- Onset at any age but more common after puberty.

**General Considerations**

Hereditary angioedema (HAE) is an autosomal dominant disorder caused by mutations in the SERPING1 gene, leading to deficiency of C1 inhibitor (C1-INH), which controls activation of the classic complement pathway, fibrinolytic and coagulation systems, and kallikrein-kinin system. Bradykinin is the most important vasoactive mediator contributing to recurrent swellings, but there is no increased susceptibility to infection. In HAE type I, C1-INH protein levels and function are decreased. In HAE type II, C1-INH protein levels are normal with decreased function. C1-INH protein and function are normal in patients with HAE type III, but they may present with mutations in the gene encoding for factor XII (F12). Acquired forms can occur with B-lymphocyte malignancies, autoantibodies against C1-INH and therefore reduced C1-INH and C1q levels, or use of an angiotensin-converting enzyme inhibitor as medication.

**Clinical Findings**

**A. Symptoms and Signs**

Affected patients can experience edema of skin and bowel and potentially life-threatening edema of the airway. Typical sites of swelling include the face, extremities, and genitals. Trauma, accidental or due to surgery, childbirth, or dental work, may induce edema. Typical problems include episodic intestinal obstruction and dental procedure–induced upper airway obstruction. The edema is usually nonpainful (unless it involves the bowel) and lasts 48–72 hours. There is no associated urticaria, redness, or pruritus. Age of onset is variable, and there is often a positive family history.

**B. Laboratory Findings**

Initial screening tests for C1-INH deficiency show a decreased CH50 or low levels of C4 and C2. C1q is usually normal. The diagnosis is confirmed by low or absent levels of C1-INH (type I, 85% of cases) or poor or absent C1-INH function (type II).

**Differential Diagnosis**

Other causes of acquired angioedema, including that associated with certain medications (most notably angiotensin-converting enzyme modifying drugs), autoimmune diseases, and lymphoproliferative diseases, should be considered. A normal level of C1q in HAE usually distinguishes this form from the acquired forms.

**Treatment**

Intravenous C1-INH concentrate is the treatment of choice for the emergency management of acute edema (eg, laryngeal or diffuse facial edema, severe abdominal attacks). Treatment with this concentrate can also be used for long-term prophylaxis.
when attacks occur monthly or have been life-threatening, or for preparation for surgery or dental work. Fresh frozen plasma may be used as a substitute in the acute situation. Synthetic androgens, for example, oxandrolone prevents attacks by increasing C1-INH levels, and this is approved for cautious use in children. Antihistamines, adrenalin, and steroids have no therapeutic value.

3. Factor H Deficiency & Atypical Hemolytic Uremic Syndrome

The effects of factor H deficiency are like those of factor I deficiency because factor H helps dismantle the alternative pathway C3-cleaving enzyme. Levels of C3, factor B, CH50, and AP50 are all decreased. Some patients have sustained serious infections, and many have had glomerulonephritis or atypical hemolytic uremic syndrome (aHUS). Mutations in genes encoding membrane control protein, factor I, factor B, C3, or the endothelial anti-inflammatory protein thrombomodulin, or autoantibodies to factor H, have also been associated with HUS. In a child with HUS, it seems advisable to screen for a complement deficiency, first with the CH50 assay. With an associated complement disorder the prognosis is less favorable, and recognizing the presence of a complement deficiency should alert the physician to the associated increased risk of infection and/or autoimmune disease.

OTHER WELL-DEFINED IMMUNODEFICIENCY SYNDROMES

1. Hyper-IgE Syndrome

Hyper-IgE syndrome (HIES), also known as Job syndrome, is a rare PID characterized by elevated levels of IgE (> 2000 IU/mL), neonatal eczematoid rash, recurrent infections with S aureus, recurrent pneumonia with pneumatocele formation, and typical facies. Mutations in a specific transcription factor, signal transducer and activator of transcription 3 (STAT3), underlie sporadic and AD forms of HIES. Additional clinical findings of HIES include retained primary teeth, scoliosis, hyperextensibility, high palate, and osteoporosis. In addition to staphylococcal infections, affected patients also have increased incidence of infections due to Streptococcus spp, Pseudomonas spp, C albicans, and even opportunistic infections with P carinii. AR HIES is associated with mutations in dedicator of cytokinesis 8 (DOCK8) and tyrosine kinase 2 (TYK2) genes. Patients with AR HIES have an increased susceptibility to viral infections, including recurrent molluscum contagiosum, warts, and herpes simplex infections. Increased susceptibility to mycobacterial infections is found in patients with TYK2 mutations. Laboratory evaluation reveals normal to profoundly elevated levels of IgE and occasionally eosinophilia. However, atopic dermatitis and parasite infection are much more common causes of elevated IgE. Diagnosis is often difficult due to variable presentation, which may become progressively severe with increasing age, but genetic testing for STAT3, DOCK8, and TYK2 mutations will help confirm the diagnosis of HIES particularly at a young age. All patients with HIES have impaired T\(_{h17}\) cell function, and measurement of T\(_{h}17^+\) cells in the peripheral blood can be used as screening test if HIES is suspected. The mainstay of treatment is prophylactic and symptomatic antibiotic use in combination with good skin care. Ig replacement has been used with some success to decrease infections and possibly modify IgE levels. Successful stem cell transplants have been conducted in DOCK8 deficiency.

2. Immune Dysregulation, Polyendocrinopathy, Enteropathy, X-Linked Syndrome

Immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome is a rare disease that usually manifests with severe diarrhea and insulin-dependent diabetes mellitus within the first months of life. Affected males also have severe eczema, food allergy, autoimmune cytopenias, lymphadenopathy, splenomegaly, and recurrent infections. Most die before 2 years of age due to malnutrition or sepsis. IPEX syndrome results from mutations in the FOXP3 gene that encodes a protein essential for developing regulatory T lymphocytes. Leukocyte counts and immunoglobulin levels are generally normal. Immunosuppression and nutritional supplementation produce temporary improvements, but the prognosis is poor and most cases result in early death. BMT has been attempted with variable success. More recently, IPEX-like syndromes have been described as associated with mutations of the gene encoding CD25, the high affinity IL-2 receptor (IL2R) which is constitutively expressed on regulatory T cells. If IPEX or IPEX-like syndromes are suspected, the presence of FOXP3\(^+\)/CD25\(^+\) regulatory T cells should be assessed not only in affected boys but also in girls. Genetic testing for FOXP3 mutations will be helpful to identify affected patients and carriers of the gene mutation.

3. X-Linked Lymphoproliferative Syndrome

X-linked lymphoproliferative syndrome is an immunodeficiency that usually develops following EBV infection. Affected males develop fulminant infectious mononucleosis with hemophagocytic syndrome, multiple organ system failure, and bone marrow aplasia. The mutated gene (SH2D1A/SAP/DSHP) encodes a signaling protein used by T lymphocytes and NK cells called SLAM-adapter protein (SAP). Affected boys are immunologically normal prior to EBV infection and during acute infection they produce antibody to EBV. In most instances, infection with EBV is fatal. Patients who survive the initial episode or who are
4. Chronic Mucocutaneous Candidiasis

Several gene defects have been associated with chronic mucocutaneous candidiasis (CMC), a disorder characterized by isolated candidal infections of the skin, nails, and mucous membranes. Systemic disease is not characteristic, but case reports of intracranial mycotic aneurysms exist. Primary CMC most commonly occurs as an isolated syndrome, but it can be associated with endocrine or autoimmune disorders. Mutations in the signal transducer and activator of transcription 3 (STAT3) gene and gain-of-function mutations in STAT1 can lead to defective T_{n17} responses, susceptibility to CMC, and *S. aureus* infections. Mutations in *IL17F* and *IL17R*, C-type lectin–associated 7 (CLEC7A or DECTIN1) or caspase recruitment domain-containing protein 9 (CARD9) cells have also been associated with CMC. An AR form of CMC with associated autoimmunity, also known as *autoimmune polyendocrinopathy, candidiasis, ectodermal dysplasia* (APECED) syndrome, is characterized by recurrent candidal infections, abnormal T-lymphocyte response to *Candida*, autoimmune endocrinopathies, and ectodermal dystrophies. APECED is caused by mutations in the gene for an important transcription regulator protein called *autoimmune regulator* (AIRE) that is critical for normal thymocyte development. In APECED, autoantibodies against IL17A and IL17F impair the T_{n17} response and contribute to CMC. Treatment of CMC includes antifungal therapy in combination with therapy for associated endocrinopathies.

5. Autoimmune Lymphoproliferative Syndrome

Autoimmune lymphoproliferative syndrome (ALPS) results from mutations of genes important for regulating programmed lymphocyte death (apoptosis). Most commonly, the defect is in Fas (CD95) or Fas ligand, but other defects in the Fas pathway have also been described (eg, caspase 10). Clinical presentation includes lymphadenopathy, splenomegaly, and autoimmune disorders (autoimmune hemolytic anemia, neutropenia, thrombocytopenia, and sometimes arthritis). Occasionally, patients have frequent infections. The diagnosis is suspected when T-lymphocyte subsets by flow cytometry demonstrate elevated numbers of CD3^+CD4^−CD8^− (double negative) T lymphocytes. Several different types of ALPS are distinguished by the response of lymphocytes to Fas-induced apoptosis. Patients are often heterozygous, and inheritance is mostly autosomal dominant. Treatment with prednisone often controls the lymphadenopathy. Infections should be treated appropriately. In some cases, BMT has been curative. Affected patients are also at risk for lymphoma. Mutations affecting another apoptosis-related protein, caspase 8, cause an ALPS variant syndrome in which the susceptibility to infection by herpes simplex virus also increases.

6. WHIM Syndrome

WHIM (warts, hypogammaglobulinemia, infection, myelokathexis) syndrome is a rare AD immunodeficiency caused by gain-of-function mutations in the gene encoding the chemokine receptor CXCR4. Patients have an increased susceptibility to viral infections (including HPV, EBV, and HSV) and recurrent bacterial infections. Laboratory evaluation reveals peripheral blood neutropenia with bone marrow hypercellularity, decreased B-cell numbers and hypogammaglobulinemia, and T-cell lymphopenia with normal CD4^+/CD8^− ratio.

7. Diseases Due to Defects in Interferon-γ & Interleukin-12 Pathways

IL-12 is a powerful inducer of interferon-γ (IFN-γ) production by T cells and NK cells. IFN-γ, and therefore the IFN-γ–IL-12 axis, is critical for macrophage activation and resistance to mycobacterial infections. Individuals with inherited deficiency in IL-12, macrophage receptors for IFN-γ, lymphocyte receptors for IL-12, or STAT1 signaling suffer a profound and selective susceptibility to infection by nontuberculous mycobacteria such as *Mycobacterium avium* complex or bacille Calmette-Guérin (BCG). About half of these patients have had disseminated salmonellosis. Treatment with supplemental IFN-γ is effective unless the IFN-γ receptor is not functional. Long-term mycobacterial prophylaxis should be considered in these individuals.

8. MonoMAC Syndrome

Disseminated infection by nontuberculous mycobacteria, viruses (ie, HPV), and fungi were recently described in association with GATA2 mutations or MonoMac (sporadic monocytopenia and mycobacterial infection) syndrome. Patients usually become symptomatic during adulthood, but younger patients may also be affected. Patients have peripheral blood monocytopenia, but presence of macrophages at sites of infections. B lymphocyte and NK cell numbers are reported low with variable T-cell numbers. This is an
autosomal dominant inherited disease with an increased risk for malignancies, especially myelodysplasia and leukemia.

9. Pattern-Recognition Receptor Defects

Pattern-recognition receptor (PRR) defects are associated with altered cytokine production and increased susceptibility to specific microbes. The clinical presentation of affected patients is most severe during infancy and early childhood with improvement of infections while patients get older, suggesting that adaptive immune responses compensate for defects in innate immunity. TLRs and members of the interleukin-1 receptor (IL-1R) family signal through IL-1R–associated kinases (IRAK) 1 and 4 while using the adaptor molecule MyD88, leading to activation of NF-κB and inflammatory cytokine production. Patients with AR deficiencies in MyD88 and IRAK-4 are predisposed to severe bacterial infections that are not associated with a high fever or significant increase in C-reactive protein at the beginning of infection. Laboratory results may reveal a decreased antibody response to polysaccharide antigens, increased IgG and IgG4 concentrations, and decreased IL-6 production upon whole blood stimulation through most TLR and IL-1R agonists. TLR3 deficiency increases susceptibility to infections with herpes simplex infections, while polymorphisms of TLR5 predispose to legionella pneumonia infections. Chronic mucocutaneous fungal infections have been linked to defects in the dectin-1/CARD9 pathway. Bacterial infections, specifically with *Neisseria meningitis*, but also viral and fungal infections can occur in context of mannose-binding lectin deficiency.

## GENETIC SYNDROMES ASSOCIATED WITH IMMUNODEFICIENCY

Several described genetic syndromes have associated immunodeficiency that is often identified after the syndrome has been diagnosed. Usually, the immune defect is not the major presenting clinical problem.

1. **Bloom Syndrome**

   Characteristics of Bloom syndrome include growth retardation, sunlight sensitivity, and telangiectasias of the face. The syndrome results from mutations in the *Blm* gene that encodes a RecQ-helicase involved in DNA repair. Affected patients present with growth retardation, microcephaly, and sun-sensitive rashes. They have an increased risk of malignancy and life-threatening infections. B- and T-cell numbers are low. Serum Igs are decreased, and T-lymphocyte function is abnormal.

2. **Transcobalamin Deficiency**

   Transcobalamin deficiency is a rare AR disease due to defective cellular transport of cobalamin associated with mutations in the *TCN2* gene. Patients present with megaloblastic anemia, diarrhea, poor growth, neurologic abnormalities, hypogammaglobulinemia, and poor specific antibody production.

3. **Immunodeficiency, Centromeric Instability, Facial Anomalies Syndrome**

   Immunodeficiency, centromeric instability, facial anomalies (ICF) syndrome is a rare AR condition caused by abnormal DNA methyltransferase. In half of the patients, a mutation can be detected in the *DNMT3B* gene. Unlike other chromosome instability syndromes, ICF syndrome does not have an associated hypersensitivity to sunlight. Affected patients have severe respiratory, gastrointestinal, and skin infections due to low or absent immunoglobulins and abnormal T-lymphocyte numbers and function.

4. **Trisomy 21**

   Patients with trisomy 21 or Down syndrome have increased susceptibility to respiratory infection. Immunodeficiency is variable, and abnormal numbers and function of T and B lymphocytes have been reported. Additionally, patients have an increased incidence of autoimmune diseases.

5. **Turner Syndrome**

   Turner syndrome (partial or complete absence of one X chromosome) is associated with increased risk of otitis media, respiratory infections, and malignancies. Immune defects are variable but may include abnormal T-lymphocyte numbers and function and hypogammaglobulinemia.

6. **Chédiak-Higashi Syndrome**

   Chédiak-Higashi syndrome is a rare AR disease caused by mutations in a lysosomal trafficking regulator (*LYST*) gene. The neutrophils of affected individuals have giant lysosomes, impaired chemotaxis, neutropenia, and abnormal NK-cell cytotoxicity. Patients present with recurrent infections (particularly periodontitis), partial oculocutaneous albinism, and neuropathy. Most patients progress to generalized lymphohistiocytic infiltration syndrome, which is a common cause of death. Treatment strategies address infections and neuropathy, and the use of immunosuppression attempts to slow lymphoproliferative progression.

7. **Griscelli Syndrome**

   Characterized by partial albinism, neutropenia, thrombocytopenia, and lymphohistiocytosis, Griscelli syndrome is a rare AR syndrome resulting from mutations in the myosin VA gene. Affected patients have recurrent and serious infections caused by fungi, viruses, and bacteria. Immunologic evaluation demonstrates variable immunoglobulin levels and antibody function with impaired T-lymphocyte function.
BMT can correct the immunodeficiency. Griscelli syndrome is distinguished from Chédiak-Higashi syndrome by the lack of granules in white blood cells.

8. Netherton Syndrome
Patients with the AR Netherton syndrome present with trichorrhexis (brittle hair), ichthyosiform rash, and allergic diseases. A subset of patients develops recurrent infections. Immune function is variable but may include hypo- or hypergamma-globulinemia, abnormal T-lymphocyte function, or abnormal phagocyte function. The disease results from mutations in a serine protease inhibitor encoded on the SPINK5 gene.

9. Cartilage-Hair Hypoplasia
Cartilage-hair hypoplasia is an AR form of chondrodysplasia manifesting with short-limbed short stature, hypoplastic hair, defective immunity, and poor erythrogenesis. The immune defect is characterized by mild to moderate lymphopenia and abnormal lymphocyte function, but normal antibody function. Affected patients have increased susceptibility to infections and increased risk of lymphoma. The disorder results from mutation in the RMRP gene that encodes the RNA component of an RNase MRP complex. BMT can restore cell-mediated immunity but does not correct the cartilage or hair abnormalities.
Endocrine Disorders

Philip S. Zeitler, MD, PhD
Sharon H. Travers, MD
Kristen Nadeau, MD
Jennifer M. Barker, MD
Megan Moriarty Kelsey, MD
Michael S. Kappy, MD, PhD

GENERAL CONCEPTS

The classic concept that endocrine effects are the result of substances secreted into the blood with effects on a distant target cell has been updated to account for other ways in which hormonal effects occur. Specifically, some hormone systems involve the stimulation or inhibition of metabolic processes in neighboring cells (eg, within the pancreatic islets or cartilage). This phenomenon is termed paracrine. Other hormone effects reflect the action of hormones on the same cells that produced them. This action is termed autocrine. The discoveries of local production of insulin, glucagon, ghrelin, somatostatin, cholecystokinin, and many other hormones in the brain and gut support the concept of paracrine and autocrine processes in these tissues.

Another significant discovery in endocrine physiology was an appreciation of the role of specific hormone receptors in target tissues, without which the hormonal effects cannot occur. For example, in the complete androgen insensitivity syndrome (AIS), androgen receptors are defective, and the 46,XY individual develops varying degrees of undervirilization of the external genitalia and internal (wolfian) duct system despite the presence of testes and adequate testosterone production. Similarly, in nephrogenic diabetes insipidus or Albright hereditary osteodystrophy (AHO [pseudohypoparathyroidism [PHP]]), affected children have defective antidiuretic hormone or parathyroid hormone (PTH) receptor function, respectively, and show the metabolic effects of diabetes insipidus or hypoparathyroidism despite more-than-adequate hormone secretion. Alternatively, abnormal activation of a hormone receptor leads to the effects of the hormone without its abnormal secretion. Examples of this phenomenon include McCune-Albright syndrome (precocious puberty and hyperthyroidism), testotoxicosis (familial male precocious puberty), and hypercalciuric hypocalcemia.

HORMONE TYPES

Hormones are of three main chemical types: peptides and proteins, steroids, and amines. The peptide hormones include the releasing factors secreted by the hypothalamus, the hormones of the anterior and posterior pituitary gland, pancreatic islet cells, parathyroid glands, lung (angiotensin II), heart and brain (atrial and brain natriuretic hormones), and local growth factors such as insulin-like growth factor 1 (IGF-1). Steroid hormones are secreted primarily by the adrenal cortex, gonads, and kidney (active vitamin D [1,25(OH)2 D3]). The amine hormones are secreted by the adrenal medulla (epinephrine) and the thyroid gland (triiodothyronine [T3] and thyroxine [T4]).

As a rule, peptide hormones and epinephrine act after binding to specific receptors on the surface of their target cell. The metabolic effects of these hormones are usually stimulation or inhibition of the activity of preexisting enzymes or transport proteins (posttranslational effects). The steroid hormones, thyroid hormone, and active vitamin D, in contrast, act more slowly and bind to cytoplasmic receptors inside the target cell and subsequently to specific regions on nuclear DNA, where they direct a read-out of specific protein(s). Their metabolic effects are generally caused by stimulating or inhibiting the synthesis of new enzymes or transport proteins (transcriptional effects), thereby increasing or decreasing the amount rather than the activity of these proteins in the target cell.

Metabolic processes that require rapid response, such as blood glucose or calcium homeostasis, are usually controlled by peptide hormones and epinephrine, while processes that respond more slowly, such as pubertal development and metabolic rate, are controlled by steroid hormones and thyroid hormone. The control of electrolyte homeostasis is intermediate and is regulated by a combination of peptide and steroid hormones (Table 34-1).
FEEDBACK CONTROL OF HORMONE SECRETION

Hormone secretion is regulated, for the most part, by feedback in response to changes in the internal environment. When the metabolic imbalance is corrected, stimulation of the hormone secretion ceases and may even be inhibited. Overcorrection of the imbalance stimulates secretion of a counterbalancing hormone or hormones, so that homeostasis is maintained within relatively narrow limits.

Hypothalamic-pituitary control of hormonal secretion is also regulated by feedback. End-organ failure (endocrine gland insufficiency) leads to decreased circulating concentrations of endocrine gland hormones and thence to increased secretion of the respective hypothalamic releasing and pituitary hormones (see Table 34–1; Figure 34–1). If restoration of normal circulating concentration of hormones occurs, feedback inhibition at the pituitary and hypothalamus results in cessation of the previously stimulated secretion of releasing and pituitary hormones and restoration of their circulating concentrations to normal.

Similarly, if there is autonomous endocrine gland hyperfunction (eg, McCune-Albright syndrome, Graves disease, or adrenal tumor), the specific hypothalamic releasing and pituitary hormones are suppressed (see Figure 34–1).

Disturbances of growth and development are the most common problems evaluated by a pediatric endocrinologist. While most cases represent normal developmental variants, it is critical to identify abnormal growth patterns, as deviations from the norm can be the first or only manifestation of an endocrine disorder. Height velocity is the most critical parameter in evaluating a child’s growth. A persistent increase or decrease in height percentiles between age 2 years and the onset of puberty always warrants evaluation. Similarly, substantial deviations from target height may be indications of underlying endocrine or skeletal disorders. It is more difficult to distinguish normal from abnormal growth in the first 2 years of life, as infants may have catch-up or catch-down growth during this period. Similarly, the variable timing of the onset of puberty makes early adolescence another period during which evaluation of growth abnormalities may require careful consideration.

Appropriate standards must be used to evaluate growth. The National Center for Health Statistics provides standard cross-sectional growth charts for North American children (see Chapter 2) and the World Health Organization (WHO) growth charts use an ethnically more diverse sample. Normal growth standards may vary with country of origin. Growth charts are available for some ethnic groups in North America and for some syndromes with specific growth disturbance such as Turner or Down syndromes.

**TARGET HEIGHT & SKELETAL MATURATION**

A child’s growth and height potential is determined largely by genetic factors. The target (midparental) height of a child is calculated from the mean parental height plus 6.5 cm for boys or minus 6.5 cm for girls. This calculation helps identify a child’s genetic growth potential. Most children achieve an adult height within 8 cm of the midparental height. Another parameter that determines growth potential is skeletal maturation or bone age. Beyond the neonatal period, bone age is evaluated by comparing a radiograph of the child’s left hand and wrist with the standards of Greulich and Pyle. Delayed or advanced bone age is not diagnostic of any specific disease, but the extent of skeletal maturation allows determination of remaining growth potential as a percentage of total height and allows prediction of ultimate height.

**SHORT STATURE**

It is important to distinguish normal variants of growth (familial short stature and constitutional growth delay) from pathologic conditions (Table 34–2). Pathologic short stature is more likely in children whose growth velocity is abnormal (crossing major height percentiles on the growth curve) or who are significantly short for their family. Children with chronic illness or nutritional deficiencies may have poor linear growth, but this is typically associated with inadequate weight gain. In contrast, endocrine causes of short stature are usually associated with normal or excessive weight gain.

1. **Familial Short Stature & Constitutional Growth Delay**

Children with familial short stature typically have normal birth weight and length. In the first 2 years of life, their linear growth velocity decelerates as they near their genetically determined percentile. Once the target percentile is reached, the child resumes normal linear growth parallel to the growth curve, usually between 2 and 3 years of age. Skeletal maturation and timing of puberty are consistent with chronologic age. The child grows along his/her own growth percentile and the final height is short but appropriate for

the family (Figure 34–2). For example, an infant boy of a mother who is 5 ft 0 in and father who is 5 ft 5 in (calculated midparental height 5 ft 5 in) may have a birth length at the 50th percentile. However, this child’s length percentile will drift downward during the first 2 years of life and will settle in at the fifth percentile where it will stay.

Children with constitutional growth delay do not necessarily have short parents but have a growth pattern similar to those with familial short stature. The difference is that children with constitutional growth delay have a delay in skeletal maturation and a delay in the onset of puberty. In these children, growth continues beyond the time the average child stops growing, and final height is appropriate for target height (Figure 34–3). There is often a history of other family members being “late bloomers.”

2. Growth Hormone Deficiency

Human growth hormone (GH) is produced by the anterior pituitary gland. Secretion is stimulated by growth hormone–releasing hormone (GHRH) and inhibited by somatostatin. GH is secreted in a pulsatile pattern in response to sleep, exercise, and hypoglycemia and has direct growth-promoting and metabolic effects (Figure 34–4). GH also promotes growth indirectly by stimulating production of insulin-like growth factors, primarily IGF-1.

Growth hormone deficiency (GHD) is characterized by decreased growth velocity and delayed skeletal maturation in the absence of other explanations. Laboratory tests indicate subnormal GH secretion or action. GHD may be isolated or coexist with other pituitary hormone deficiencies and may be congenital (septo-optic dysplasia or ectopic posterior pituitary), genetic (GH or GHRH gene mutation), or acquired (craniopharyngioma, germinoma, histiocytosis, or cranial irradiation). Idiopathic GHD is the most common deficiency state with an incidence of about 1:4000 children. Patients have also been described with a GH resistance syndrome caused by mutations in the GH receptor or other components of the GH signaling pathway. The presentation of GH resistance is similar to that of GHD, but short stature is often severe, with little or no response to GH therapy. Some mutations, such as Laron dwarfism, are accompanied by facial and skeletal dysmorphology.

Infants with GHD have normal birth weight with only slightly reduced length, suggesting that GH is a minor contributor to intrauterine growth. GH deficient infants may present with hypoglycemia, particularly when associated with other pituitary deficiencies such as central adrenal insufficiency. Micropenis may be a feature of newborn males with gonadotropin and GH deficiency. Isolated GHD and hypopituitarism may be unrecognized until late in infancy or childhood as growth retardation may be delayed until later childhood. Regardless of onset, the primary manifestation of idiopathic or acquired GHD is subnormal growth velocity.
Typical pattern of growth in a child with familial short stature. After attaining an appropriate percentile during the first 2 years of life, the child will have normal linear growth parallel to the growth curve. Skeletal maturation and the timing of puberty are consistent with chronologic age. The height percentile the child has been following is maintained, and final height is short but appropriate for the family.
**Figure 34-3.** Typical pattern of growth in a child with constitutional growth delay. Growth slows during the first 2 years of life, similarly to children with familial short stature. Subsequently the child will have normal linear growth parallel to the growth curve. However, skeletal maturation and the onset of puberty are delayed. Growth continues beyond the time the average child has stopped growing, and final height is appropriate for target height.
The effects of GH on growth are partly due to its direct anabolic effects in muscle, liver, and bone. In addition, GH stimulates many tissues to produce IGF-1 locally, which stimulates the growth of the tissue itself (paracrine effect of IGF-1). The action of GH on the liver results in the secretion of IGF-1 (circulating IGF-1), which stimulates growth in other tissues (endocrine effect of IGF-1). The action of growth hormone on the liver also enhances the secretion of IGF-binding protein 3 (IGFBP-3) and acid-labile subunit (ALS), which form a high-molecular-weight complex with IGF-1. The function of this complex is to transport IGF-1 to its target tissues, but the complex also serves as a reservoir and possible inhibitor of IGF-1 action. In various chronic illnesses, the direct metabolic effects of GH are inhibited; the secretion of IGF-1 in response to GH is blunted, and in some cases IGFBP-3 synthesis is enhanced, resulting in marked inhibition in the growth of the child. IGF-1, insulin-like growth factor 1; GH, growth hormone; GHRH, growth hormone–releasing hormone.

Laboratory tests to assess GH status may be difficult to interpret. Children with normal short stature have a broad range of GH secretion patterns and there is significant overlap between normal and GH deficient children. Random samples for measurement of serum GH are of no value in the diagnosis of GHD, as GH secretion is pulsatile. Serum concentrations of IGF-1 give reasonable estimations of GH secretion and action in the adequately nourished child (see Figure 34–4), and are often used as a first step in the evaluation for GHD. IGF-binding protein 3 (IGFBP-3) is a much less sensitive marker of GH deficiency, but may be useful in the underweight child or in children under 4 years of age, since it is less affected by age or nutritional status. Provocative studies using such agents as insulin, arginine, levodopa, clonidine, or glucagon are traditionally done to clarify GH secretion, but are not physiologic and are often poorly reproducible, ultimately limiting their value in the clarification of GH secretion. When results of GH tests are equivocal and the clinical suspicion very high, a trial of GH treatment may help determine whether an abnormally short child will benefit from GH. Currently, the recommended treatment schedule for GHD is subcutaneous recombinant GH given subcutaneously 7 days per week with total weekly dose of 0.15–0.3 mg/kg.

GH therapy is approved by the U.S. Food and Drug Administration (FDA) for children with GHD and growth restriction associated with chronic renal failure, for girls with Turner syndrome, children with Prader-Willi and Noonan’s syndromes, and children born small for gestational age (SGA) who fail to demonstrate catch-up growth by age 4. Dose ranges for these non-GHD indications are generally different than for GHD (lower doses with Prader-Willi syndrome, higher doses with Turner syndrome and SGA). GH therapy has also been approved for children.
▲ Figure 34–5. Typical pattern of growth in a child with acquired growth hormone deficiency (GHD). Children with acquired GHD have an abnormal growth velocity and fail to maintain height percentile during childhood. Other phenotypic features (central adiposity and immaturity of facies) may be present. Children with congenital GHD will cross percentiles during the first 2 years of life, similarly to the pattern seen in familial short stature and constitutional delay, but will fail to attain a steady height percentile subsequently.
with idiopathic short stature whose current height is more than 2.25 standard deviations below the normal range for age. Final height may be 5–7 cm taller in this population. This last indication is controversial and the role of GH for idiopathic short stature is still unclear, especially due to the expense, long duration of treatment, and unclear psychological consequences. Side effects of recombinant GH are uncommon but include benign intracranial hypertension and slipped capital femoral epiphysis. With early diagnosis and treatment, children with GHD reach normal or near-normal adult height. Recombinant IGF-1 injections may be used to treat children with GH resistance or IGF-1 deficiency, but improvements in growth are not as substantial as seen with GH therapy for GH deficiency.

3. Small for Gestational Age/Intrauterine Growth Restriction

SGA infants have birth weights below the 10th percentile for the population’s birth weight–gestational age relationship. SGA infants include constitutionally small infants and infants with intrauterine growth restriction (IUGR).

SGA/IUGR may be a result of poor maternal environment, intrinsic fetal abnormalities, congenital infections, or fetal malnutrition. Intrinsic fetal abnormalities causing SGA/IUGR (often termed primordial short stature) include Russell-Silver, Seckel, Noonan, Bloom, and Cockayne syndromes, and progeria. Many children with mild SGA/IUGR and no intrinsic fetal abnormalities exhibit catch-up growth during the first 3 years. However, 15%–20% remain short throughout life, particularly those whose growth restriction in utero occurred over more than just the last 2–3 months of gestation. Catch-up growth may also be inadequate in preterm SGA/IUGR infants with poor postnatal nutrition. Children who do not show catch-up growth may have normal growth velocity, but follow a lower height percentile than expected for the family. In contrast to children with constitutional growth delay, those with SGA/IUGR have skeletal maturation that corresponds to chronologic age or is only mildly delayed.

GH therapy for SGA/IUGR children with growth delay is FDA approved and appears to increase growth velocity and final adult height.

4. Disproportionate Short Stature

There are more than 200 sporadic and genetic skeletal dysplasias that may cause disproportionate short stature. Measurements of arm span and upper-to-lower body segment ratio are helpful in determining whether a child has normal body proportions. If disproportionate short stature is found, a skeletal survey may be useful to detect specific radiographic features characteristic of some disorders. The effect of GH on most of these rare disorders is unknown.

5. Short Stature Associated With Syndromes

Short stature is associated with many syndromes, including Turner, Down, Noonan, and Prader-Willi. Girls with Turner syndrome often have recognizable features such as micrognathia, webbed neck, low posterior hairline, edema of hands and feet, multiple pigmented nevi, and an increased carrying angle. However, short stature can be the only obvious manifestation of Turner syndrome. Consequently, any girl with unexplained short stature for family warrants a chromosomal evaluation. Although girls with Turner syndrome are not usually GH deficient, GH therapy can improve final height by an average of 6.0 cm. Duration of GH therapy is a significant predictor of long-term height gain; consequently, it is important that Turner syndrome be diagnosed early and GH started as soon as possible.

GH is approved for treatment of growth failure in Prader-Willi syndrome. Many affected individuals are GH deficient and GH improves growth, body composition, and physical activity. A few deaths have been reported in Prader-Willi children receiving GH, all of which occurred in very obese children, children with respiratory impairments, sleep apnea, or unidentified respiratory infections. The role of GH, if any, in these deaths is unknown. However, as a precaution, it is recommended that all Prader-Willi patients be evaluated for upper airway obstruction and sleep apnea prior to starting GH therapy.

Children with Down syndrome should be evaluated for GHD only if their linear growth is abnormal compared with the Down syndrome growth chart.

6. Psychosocial Short Stature (Psychosocial Dwarfism)

Psychosocial short stature refers to growth retardation associated with emotional deprivation. Undernutrition probably contributes to growth retardation in some of these children. Other symptoms include unusual eating and drinking habits, bowel and bladder incontinence, social withdrawal, and delayed speech. GH secretion in children with psychosocial short stature is diminished, but GH therapy is usually not beneficial. A change in the psychological environment at home usually results in improved growth and improvement of GH secretion, personality, and eating behaviors.

Clinical Evaluation

Laboratory investigation should be guided by the history and physical examination. Data included in history and physical include history of chronic illness and medications, birth weight and height, pattern of growth since birth, familial growth patterns, pubertal stage, dysmorphic features, body segment proportion, and psychological health. In a child with
poor weight gain as the primary disturbance, a nutritional assessment is indicated. The following laboratory tests may be useful as guided by history and clinical judgment:

1. Radiograph of left hand and wrist for bone age
2. Complete blood count (to detect chronic anemia or leukocyte markers of infection)
3. Erythrocyte sedimentation rate (often elevated in collagen-vascular disease, cancer, chronic infection, and inflammatory bowel disease)
4. Urinalysis, blood urea nitrogen, and serum creatinine (occult renal disease)
5. Serum electrolytes, calcium, and phosphorus (renal tubular disease and metabolic bone disease)
6. Stool examination for fat, or measurement of serum tissue transglutaminase (malabsorption or celiac disease)
7. Karyotype (girls) and/or Noonan’s testing
8. Thyroid function tests: thyroxine (T4) and thyroid-stimulating hormone (TSH)
9. IGF-1 (IGFBP-3 is an alternative for children < 4 or in malnourished individuals)

Because the upper limit of acceptable height in both sexes is increasing, concerns about excessive growth in girls are less frequent than in the past. When such concerns arise, the family history, growth curve, pubertal stage, and assessment of skeletal maturation allow estimation of final adult height. Reassurance, counseling, and education may alleviate family and personal concerns. Rarely, when the predicted height is excessive and felt to be psychologically unacceptable, brief estrogen therapy may be used to accelerate bone maturation and shorten the growth period.

ARGinine VAsopressin (Antidiuretic Hormone) PHYSIOLOGY

Vasopressin release is controlled primarily by serum osmolality and intravascular volume. Release is stimulated by minor increases in plasma osmolality (detected by osmo-receptors in the anterolateral hypothalamus) and large decreases in intravascular volume (detected by baroreceptors in the cardiac atria). Disorders of vasopressin release and action include (1) central (neurogenic) diabetes insipidus, (2) nephrogenic diabetes insipidus (see Chapter 24),
and (3) the syndrome of inappropriate secretion of antidiuretic hormone (see Chapter 45).

CENTRAL DIABETES INSIPIDUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Polydipsia, polyuria (> 2 L/m²/d), nocturia, dehydration, and hypernatremia.
- Inability to concentrate urine after fluid restriction (urine specific gravity < 1.010; urine osmolality < 300 mOsm/kg).
- Plasma osmolality > 300 mOsm/kg with urine osmolality < 600 mOsm/kg.
- Low plasma vasopressin with antidiuretic response to exogenous vasopressin.

General Considerations

Central diabetes insipidus (DI) is an inability to synthesize and release vasopressin. Without vasopressin, the kidneys cannot concentrate urine, causing excessive urinary water loss. Genetic causes of central DI are rare and include mutations in the vasopressin gene (mostly in the neurophysin portion of the vasopressin precursor) and the WFS1 gene that causes DI, diabetes mellitus, optic atrophy, and deafness (Wolfram or DIDMOAD syndrome). Transcription factor mutations, such as PROP1 and PIT1, that are known to be associated with other anterior pituitary hormone deficiencies are not typically associated with DI. Midline brain abnormalities, such as septo-optic dysplasia and holoprosencephaly, are also associated with central DI. Traumatic brain injury or neurosurgery in or near the hypothalamus or pituitary can cause transient or permanent DI. Traumatic DI often has three phases. Initially, transient DI is caused by edema in the hypothalamus or pituitary area. In 2–5 days, unregulated release of vasopressin from dying neurons causes the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Finally, permanent DI occurs if a sufficient number of vasopressin neurons are destroyed.

Tumors and infiltrative diseases of the hypothalamus and pituitary may cause DI. In children with craniopharyngioma, DI usually develops after neurosurgical intervention. In contrast, germinomas often present with DI. Germinomas may be undetectable for several years; consequently, children with unexplained DI should have regularly repeated magnetic resonance imaging (MRI). Infiltrative diseases such as histiocytosis and lymphoctic hypophysitis can cause DI. In these conditions, as in germinomas, MRI scans characteristically show thickening of the pituitary stalk. Infections involving the base of the brain also cause transient DI.

Clinical Findings

Onset of DI is often abrupt, characterized by polyuria, nocturia, enuresis, and intense thirst. Children with DI typically crave cold water. Hypernatremia, hyperosmolality, and dehydration occur if insufficient fluid intake due to lack of access or impaired thirst mechanism does not keep up with urinary losses. In infants, symptoms may also include failure to thrive, vomiting, constipation, and unexplained fevers. Some infants may present with severe dehydration, circulatory collapse, and seizures. Vasopressin deficiency may be masked in patients with panhypopituitarism due to the impaired excretion of free water associated with adrenal insufficiency. Treating these patients with glucocorticoids may unmask their DI.

DI is confirmed when serum hyperosmolality is associated with urine hypoosmolality. If the history indicates that the child can go through the night comfortably without drinking, outpatient testing is appropriate. Oral fluid intake is prohibited after midnight. Osmolality, sodium, and specific gravity of the first morning void are obtained. If urine specific gravity is greater than 1.015, DI is excluded. If urine is not concentrated, a blood sample is obtained within a few minutes of the urine collection for osmolality, sodium, creatinine, and calcium concentration.

If screening results are unclear or if symptoms preclude safely withholding fluids at home, a water deprivation test performed in the hospital is indicated. In this test, fluid is withheld and the child is monitored. Serum osmolality greater than 290 mOsm/kg associated with inappropriately dilute urine (osmolality less than 600 mOsm/kg) is diagnostic for DI. Low serum vasopressin concentration and an antidiuretic response to vasopressin administration at the end of the test distinguishes central from nephrogenic DI. Children with central DI should have a head MRI scan with contrast to look for tumors or infiltrative processes. The posterior pituitary “bright spot” on MRI is often absent in DI.

Primary polydipsia must be distinguished from DI. Children with primary polydipsia tend to have lower serum sodium levels and usually can concentrate their urine with overnight fluid deprivation. Some may have secondary nephrogenic DI due to dilution of the renal medullary interstitium and decreased renal concentrating ability, but this resolves with restriction of fluid intake.

Treatment

Central DI is treated with oral or intranasal desmopressin acetate (DDAVP). The aim of therapy is to provide antidiuresis that allows uninterrupted sleep and approximately 1 hour of diuresis before the next dose. It is important to note that postsurgical DI can be associated with disruption of thirst mechanism and, for these patients, a prescribed volume of fluid intake needs to be determined. Children hospitalized with acute-onset DI can be managed with intravenous vasopressin. Due to the amount of antidiuresis, intravenous fluids
will need to be restricted to two-thirds the maintenance rate and electrolytes closely monitored to avoid water intoxication. Infants with DI should not be treated with DDAVP. Treatment with DDAVP in association with the volume of formula or breast milk needed to ensure adequate caloric intake could cause water intoxication. For this reason, infants are treated with extra free water, rather than DDAVP, to maintain normal hydration. A formula with a low renal solute load and chlorothiazides may be helpful in infants with central DI.

THYROID GLAND

FETAL DEVELOPMENT OF THE THYROID

The fetal thyroid synthesizes thyroid hormone as early as the 10th week of gestation. Thyroid hormone appears in the fetal serum by the 11th week of gestation and progressively increases throughout gestation. The fetal pituitary-thyroid axis functions largely independently of the maternal pituitary-thyroid axis because maternal TSH cannot cross the placenta. However, maternal thyroid hormone can cross the placenta in limited amounts.

At birth, there is a TSH surge peaking at about 70 mU/L within 30–60 minutes. Thyroid hormone serum level increases rapidly during the first days of life in response to this TSH surge. The TSH level decreases to childhood levels within a few weeks. The physiologic neonatal TSH surge can produce a false-positive newborn screen for hypothyroidism (ie, high TSH) if the blood sample for the screen is collected on the first day of life.

PHYSIOLOGY

Hypothalamic thyrotropin-releasing hormone (TRH) stimulates the anterior pituitary gland to release TSH. In turn, TSH stimulates the thyroid gland to take up iodine, and to synthesize and release the active hormones, thyroxine (T₄) and triiodothyronine (T₃). This process is regulated by negative feedback involving the hypothalamus, pituitary, and thyroid (see Figure 34–1).

T₄ is the predominant thyroid hormone secreted by the thyroid gland. Most circulating T₃ and T₄ are bound to thyroxine-binding globulin (TBG), albumin, and prealbumin. Less than 1% of T₄ and T₃ exist as free T₃ (FT₃) and free T₄ (FT₄). T₃ is deiodinated in the tissues to either T₂ (active) or reverse T₃ (inactive). In peripheral tissues, T₂ binds to high-affinity nuclear thyroid hormone receptors in the cytoplasm and translocates to the nucleus, exerting its biologic effects by modifying gene expression.

The T₄ level is low in hypothyroidism. It may also be low in premature infants, malnutrition, severe illness, and following therapy with T₃. It is not clear whether premature infants with low T₄ benefit from treatment. Long-term studies have been proposed to assess cognitive outcomes for high-risk patients.

Total T₄ is also low in situations that decrease TBG. TBG levels are decreased in familial TBG deficiency, nephrosis, and in patients receiving androgens. In sepsis, TBG cleavage is increased. Treatment with certain medications (heparin, furosemide, salicylates, and phenytoin) results in abnormal binding to TBG. However, since these effects involve primarily TBG levels, and not thyroid function per se, TSH and FT₄ levels remain in the normal range. Conversely, Total T₃ and T₄ levels may be elevated in conditions associated with increased TBG levels (congenital TBG excess, pregnancy, estrogen therapy) and increased thyroid hormone binding to transport proteins. However, free hormone levels are not affected and patients are euthyroid.

HYPOTHYROIDISM (CONGENITAL & ACQUIRED)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Growth retardation, decreased physical activity, weight gain, constipation, dry skin, cold intolerance, and delayed puberty.
- Neonates with congenital hypothyroidism often look normal but may have thick tongue, large fontanelles, poor muscle tone, hoarseness, umbilical hernia, jaundice, and intellectual retardation.
- T₄, FT₄, and T₃ resin uptake are low; TSH levels are elevated in primary hypothyroidism.

General Considerations

Thyroid hormone deficiency may be congenital or acquired (Table 34–4). It can be due to defects in the thyroid gland (primary hypothyroidism) or in the hypothalamus or pituitary (central hypothyroidism).

Congenital hypothyroidism occurs in about 1:3000–1:4000 infants. Untreated, it causes severe neurocognitive impairment.
Most cases are sporadic resulting from hypoplasia or aplasia of the thyroid gland or failure of the gland to migrate to its normal anatomic location (ie, lingual or sublingual thyroid gland). Another cause of congenital hypothyroidism is dysmorphogenenic due to enzymatic defects in thyroid hormone synthesis. Since antithyroid drugs, including propylthiouracil (PTU) and methimazole, freely cross the placenta, goitrous hypothyroid newborns may be born to hyperthyroid mothers treated with these drugs during pregnancy.

Low T₄ levels may also be caused by decreased TSH secretion associated with prolonged glucocorticoid use, dopamine, or somatostatin. Cabbage, soybeans, aminosalicylic acid, thiourea derivatives, resorcinol, phenylbutazone, cobalt, and excessive iodine intake can cause goiter and hypothyroidism during pregnancy. Many of these agents cross the placenta and should be used with caution during pregnancy. Iodine deficiency also causes hypothyroidism. In severe maternal iodine deficiency, both the fetus and the mother are T₄-deficient, with irreversible brain damage in the fetus.

Juvenile hypothyroidism, particularly if goiter is present, is usually a result of chronic lymphocytic (Hashimoto) thyroiditis.

Several hundred patients with resistance to thyroid hormone have been described and present with elevations in T₄ and/or FT₄ with normal TSH. There is often a family history of the disorder. Clinical manifestations are highly variable due to differential expression of thyroid hormone receptor isoforms in different tissues.

### Clinical Findings

#### A. Symptoms and Signs

Even when the thyroid gland is completely absent, most newborns with congenital hypothyroidism appear normal at birth and gain weight normally for the first few months of life without treatment. Since congenital hypothyroidism must be treated as early as possible to prevent intellectual impairment, the diagnosis should be based on the newborn screening test and not on signs or symptoms. Jaundice associated with an unconjugated hyperbilirubinemia may be present in newborns with congenital hypothyroidism. Some infants may have obvious findings of thick tongue, hypotonia, large fontanels, constipation, umbilical hernia, hoarse cry, and dry skin.

Juvenile hypothyroidism often presents with short stature and abnormal weight gain. Other findings include delayed epiphyseal development, delayed closure of fontanels, and retarded dental eruption. The skin may be dry, thick, scaly, coarse, pale, cool, or mottled, or have a yellowish tinge. The hair may be dry, coarse, or brittle. Lateral thinning of the eyebrows may occur. Musculoskeletal findings include hypotonia and a slow relaxation component of deep tendon reflexes (best appreciated in the ankles). Muscular hypertrophy (Kocher-Debré-Sémélaigne syndrome) is not commonly seen in congenital hypothyroidism. Other findings include physical and mental sluggishness, nonpitting myxedema, constipation, large tongue, hypothermia, bradycardia, hoarse voice or cry, umbilical hernia, and transient deafness. Puberty may be delayed. Metromenorrhagia may occur in older girls. Sometimes, hypothyroidism induces pseudopuberty. Galactorrhea can also occur, due to stimulation of prolactin secretion.

In hypothyroidism resulting from enzymatic defects, ingestion of goitrogens, or chronic lymphocytic thyroiditis, the thyroid gland may be enlarged. Thyroid enlargement in

| b. Goitrogens (propylthiouracil, methimazole) | Cabbage, soybeans, aminosalicylic acid, thiourea derivatives, resorcinol, phenylbutazone, cobalt, and excessive iodine intake can cause goiter and hypothyroidism during pregnancy. Many of these agents cross the placenta and should be used with caution during pregnancy. Iodine deficiency also causes hypothyroidism. In severe maternal iodine deficiency, both the fetus and the mother are T₄-deficient, with irreversible brain damage in the fetus.

Juvenile hypothyroidism, particularly if goiter is present, is usually a result of chronic lymphocytic (Hashimoto) thyroiditis.

Several hundred patients with resistance to thyroid hormone have been described and present with elevations in T₄ and/or FT₄ with normal TSH. There is often a family history of the disorder. Clinical manifestations are highly variable due to differential expression of thyroid hormone receptor isoforms in different tissues.
children is usually symmetrical, and the gland is moderately firm and not nodular. In chronic lymphocytic thyroiditis, however, the thyroid frequently has a cobblestone surface.

B. Laboratory Findings
Total T4 and FT4 levels are decreased. T3 resin uptake (T3RU) is low. In primary hypothyroidism, the serum TSH level is elevated. In central hypothyroidism, the TSH level may be low or inappropriately normal. Circulating autoantibodies to thyroid peroxidase and thyroglobulin may be present. Serum prolactin may be elevated, resulting in galactorrhea. Serum GH may be decreased, with subnormal GH response to stimulation in children with severe primary hypothyroidism, as well as low IGF-1 or IGFBP-3 levels, or both.

C. Imaging
Thyroid imaging, while helpful in establishing the cause of congenital hypothyroidism, does not affect the treatment plan and is not necessary. Bone age is delayed. Centers of ossification, especially of the hip, may show multiple small centers or a single stippled, porous, or fragmented center (epiphyseal dysgenesis). Cardiomegaly is common. Longstanding primary hypothyroidism may be associated with thyrotrophic hyperplasia characterized by an enlarged sella or pituitary gland.

D. Screening Programs for Neonatal Hypothyroidism
All newborns should be screened for congenital hypothyroidism shortly after birth as most do not have suggestive physical findings. Depending on the state, the newborn screen measures either the total T4 or TSH level. Abnormal newborn screening results should be confirmed immediately with a T4 and TSH level. Treatment should be started as soon as possible. Initiation of treatment in the first month of life and good compliance during infancy usually results in a normal neurocognitive outcome.

E. Conditions Associated With Hypothyroidism
Children with Down syndrome, Turner syndrome, and autoimmune diseases such as celiac disease, vitiligo, alopecia, and type 1 diabetes are at an increased risk for the development of acquired autoimmune hypothyroidism. A detailed family history may reveal the presence of multiple autoimmune diseases in the family members of the affected individual. Individuals at a high risk based on a chromosomal disorder or other autoimmune disease benefit from careful monitoring of growth and development, routine screening (in the case of Down syndrome, Turner syndrome, and type 1 diabetes), and a low threshold for measurement of thyroid function.

Central hypothyroidism is associated with other disorders of the hypothalamus and pituitary including congenital defects such as septo-optic dysplasia and acquired defects such as tumors in the hypothalamic/pituitary region.

Treatment
Levothyroxine (75–100 mcg/m2/d) is the drug of choice for acquired hypothyroidism. In neonates with congenital hypothyroidism, the initial dose is 10–15 mcg/kg/d. Serum total T4 or FT4 concentrations are used to monitor the adequacy of initial therapy because the normally high neonatal TSH may not normalize for several days to weeks. Subsequently, T4 and TSH are used in combination, as elevations of serum TSH are sensitive early indicators of the need for increased medication or better compliance.

(and other endocrine autoimmune disorders) is associated with certain histocompatibility alleles.

**Clinical Findings**

**A. Symptoms and Signs**

The thyroid is characteristically enlarged, firm, freely movable, nontender, and symmetrical. It may be nodular. Onset is usually insidious. Occasionally patients note a sensation of tracheal compression or fullness, hoarseness, and dysphagia. No local signs of inflammation or systemic infection are present. Most patients are euthyroid. Some patients are symptomatically hypothyroid, and few patients are symptomatically hyperthyroid.

**B. Laboratory Findings**

Laboratory findings vary. Serum concentrations of TSH, T\(_4\), and FT\(_4\) are usually normal. Some patients are hypothyroid with an elevated TSH and low thyroid hormone levels. A few patients are hyperthyroid with a suppressed TSH and elevated thyroid hormone levels. Thyroid antibodies (antithyroglobulin, antithyroid peroxidase) are frequently elevated. Thyroid uptake scan adds little to the diagnosis. Surgical or needle biopsy is diagnostic but seldom necessary.

**Treatment**

There is controversy about the need to treat chronic lymphocytic thyroiditis with normal thyroid function. Full replacement doses of thyroid hormone may decrease the size of the thyroid, but may also result in hyperthyroidism. Hypothyroidism commonly develops over time. Consequently, patients require lifelong surveillance. Children with documented hypothyroidism should receive thyroid hormone replacement.

**Hypothyroidism**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Nervousness, emotional lability, hyperactivity, fatigue, tremor, palpitations, excessive appetite, weight loss, increased perspiration, and heat intolerance.
- Goiter, exophthalmos, tachycardia, widened pulse pressure, systolic hypertension, weakness, and smooth, moist, warm skin.
- TSH is suppressed. Thyroid hormone levels (T\(_4\), FT\(_4\), T\(_3\), T\(_3\)RU) are elevated.

**General Considerations**

In children, most cases of hyperthyroidism are due to Graves disease, caused by antibodies directed at the TSH receptor that stimulate thyroid hormone production. Hyperthyroidism may also be due to acute, subacute, or chronic thyroiditis; autonomous functioning thyroid nodules; tumors producing TSH; McCune-Albright syndrome; exogenous thyroid hormone excess; and acute iodine exposure.

**Clinical Findings**

**A. Symptoms and Signs**

Hyperthyroidism is more common in females than males. In children, it most frequently occurs during adolescence. The course of hyperthyroidism tends to be cyclic, with spontaneous remissions and exacerbations. Symptoms include worsening school performance, poor concentration, fatigue, hyperactivity, emotional lability, nervousness, personality disturbance, insomnia, weight loss (despite increased appetite), palpitations, heat intolerance, increased perspiration, diarrhea, polyuria, and irregular menses. Signs include tachycardia, systolic hypertension, increased pulse pressure, tremor, proximal muscle weakness, and moist, warm, skin. Accelerated growth and development may occur. Thyroid storm is a rare condition characterized by fever, cardiac failure, emesis, delirium, coma, and death. Most cases of Graves disease are associated with a diffuse firm goiter. A thyroid
bruin and thrill may be present. Many cases are associated with exophthalmos, but severe ophthalmopathy is rare.

B. Laboratory Findings
TSH is suppressed. $T_4$, FT$_4$, T$_3$, and FT$_3$ are elevated except in rare cases in which only the serum T$_3$ is elevated (T$_3$ thyrotoxicosis). The presence of thyroid-stimulating immunoglobulin (TSI) confirms the diagnosis of Graves disease. TSH receptor–binding antibodies (TRaB) are usually elevated.

C. Imaging
In Graves disease, radioactive iodine uptake by the thyroid is increased, whereas in subacute and chronic thyroiditis it is decreased. An autonomous hyperfunctioning nodule takes up iodine and appears as a “hot nodule” while the surrounding tissue has decreased iodine uptake. In children with hyperthyroidism, bone age may be advanced. In infants, accelerated skeletal maturation may be associated with premature fusion of the cranial sutures. Long-standing hyperthyroidism causes osteoporosis.

Differential Diagnosis
Hypermethabolic states (severe anemia, chronic infections, pheochromocytoma, and muscle-wasting disease) may resemble hyperthyroidism clinically but differ in thyroid function tests.

Treatment
A. General Measures
In untreated hyperthyroidism, strenuous physical activity should be avoided. Bed rest may be required in severe cases.

B. Medical Treatment
1. $\beta$-Adrenergic blocking agents—These agents are adjuncts to therapy. They can rapidly ameliorate symptoms such as nervousness, tremor, and palpitations, and are indicated in severe disease with tachycardia and hypertension. $\beta_1$ Specific agents such as atenolol are preferred because they are more cardioselective.

2. Antithyroid agents (propylthiouracil and methimazole)—Antithyroid agents are frequently used in the initial treatment of childhood hyperthyroidism. These drugs interfere with thyroid hormone synthesis, and usually take a few weeks to produce a clinical response. Adequate control is usually achieved within a few months. If medical therapy is unsuccessful, more definitive therapy, such as radioablation of the thyroid or thyroidectomy, should be considered.

In response to reports of severe hepatotoxicity related to PTU, recent recommendations state that PTU should not be used in infants, children, or adolescents, except when methimazole is contraindicated due to hypersensitivity or pregnancy.

a. Initial dosage—Methimazole is initiated at a dose of 10–60 mg/d (0.5–1 mg/kg/d) given once a day. Initial dosing is continued until FT$_4$ or T$_4$ have normalized and signs and symptoms have subsided.

b. Maintenance—The optimal dose of antithyroid agent for maintenance treatment remains unclear. Recent studies suggest that 10–15 mg/d of methimazole provides adequate long-term control in most patients with a minimum of side effects. If the TSH becomes elevated, many providers decrease the dose of the antithyroid agent. Some providers continue the same dose of antithyroid agent and add exogenous thyroid hormone replacement. Treatment usually continues for 2 years with the goal of inducing remission. If thyroid hormone levels are stable, a trial off medication could be considered at that point.

c. Toxicity—If rash, vasculitis, arthralgia, arthritis, granulocytopenia, or hepatitis occur, the drug must be discontinued.

3. Iodide—Large doses of iodide usually produce a rapid but short-lived blockade of thyroid hormone synthesis and release. This approach is recommended only for acute management of severely thyrotoxic patients.

C. Radiation Therapy
Radioactive iodine ablation of the thyroid is usually reserved for children with Graves disease who do not respond to antithyroid agents, develop adverse effects from the antithyroid agents, fail to achieve remission after several years of medical therapy, or have poor medication adherence. With recent concerns regarding potential hepatotoxicity of antithyroid medications, some pediatric endocrinologists advocate radioablation as first-line therapy for children with Graves disease. Antithyroid agents should be discontinued 4–7 days prior to radioablation to allow radioiodine uptake by the thyroid. $^{131}$I is administered orally which concentrates in the thyroid and results in gradual ablation of the gland. In the first 2 weeks following radioablation, hyperthyroidism may worsen as thyroid tissue is destroyed and thyroid hormone is released. Therapy with a $\beta$-adrenergic antagonist may be necessary for a few months until FT$_4$ and T$_4$ fall into the normal range. In most cases, hypothyroidism develops and thyroid hormone replacement is needed. Long-term follow-up studies have not shown any increased incidence of thyroid cancer, leukemia, infertility, or birth defects when ablative doses of $^{131}$I were used.

D. Surgical Treatment
Subtotal and total thyroidectomy are infrequently used in children with Graves disease. Surgery is indicated for
extremely large goiters, goiters with a suspicious nodule, very young or pregnant patients, or patients refusing radioiodine ablation. Before surgery, a β-adrenergic blocking agent is given to treat symptoms, and antithyroid agents are given for several weeks to minimize the surgical risks associated with hyperthyroidism. Iodide (eg, Lugol solution, 1 drop every 8 hours, or saturated solution of potassium iodide, 1–2 drops daily) is given for 1–2 weeks prior to surgery to reduce thyroid vascularity and inhibit release of thyroid hormone. Surgical complications include hypoparathyroidism, recurrent laryngeal nerve damage, and rarely, death. An experienced thyroid surgeon is crucial to good surgical outcome. After thyroidectomy, patients become hypothyroid and need thyroid hormone replacement.

**Course & Prognosis**

Partial remissions and exacerbations may continue for several years. Treatment with an antithyroid agent results in prolonged remissions in one-third to two-thirds of children.

**Neonatal Graves Disease**

Transient congenital hyperthyroidism (neonatal Graves disease) occurs in about 1% of infants born to mothers with Graves disease. It occurs when maternal TSH receptor antibodies cross the placenta and stimulate excess thyroid hormone production in the fetus and newborn. Neonatal Graves disease can be associated with irritability, IUGR, poor weight gain, flushing, jaundice, hepatosplenomegaly, and thrombocytopenia. Severe cases may result in cardiac failure and death. Hyperthyroidism may develop several days after birth, especially if the mother was treated with PTU (which crosses the placenta). Symptoms develop as PTU levels decline in the newborn. Thyroid studies should be obtained at birth and repeated within the first week. Immediate management should focus on the cardiac manifestations. Temporary treatment may be necessary with iodide, antithyroid agents, β-adrenergic antagonists, or corticosteroids. Hyperthyroidism gradually resolves over 1–3 months as maternal antibodies decline. As TSH receptor antibodies may still be present in the serum of previously hyperthyroid mothers after thyroidectomy or radioablation, neonatal Graves disease should be considered in all infants of mothers with a history of hyperthyroidism.

**THYROID CANCER**

Thyroid cancer is rare in childhood. Children usually present with a thyroid nodule or an asymptomatic asymmetrical neck mass. Dysphagia and hoarseness are unusual symptoms. Thyroid function tests are usually normal. A “cold” nodule is often seen on a technetium or radioiodine uptake scan of the thyroid. Fine-needle aspiration biopsy of the nodule assists in the diagnosis.

The most common thyroid cancer is papillary thyroid carcinoma, a well-differentiated carcinoma arising from the thyroid follicular cell. Children frequently present with local metastases to the cervical lymph nodes and occasionally with pulmonary metastases. Despite its aggressive presentation, children with papillary thyroid carcinoma have a relatively good prognosis, with a 20-year survival rate greater than 90%. Treatment consists of total thyroidectomy and removal of all involved lymph nodes, usually followed by radioiodine ablation to destroy residual thyroid remnant and metastatic tissue left behind after surgery. Thyroid hormone replacement is started to suppress TSH secretion and stimulation of residual thyroid tissue and to treat the hypothyroidism that results from surgical removal of the thyroid gland. Since papillary thyroid carcinoma in children is associated with a high recurrence rate, regular follow-up with serum thyroglobulin levels (a tumor marker), neck ultrasound, and radioiodine whole body scan are required.

Follicular thyroid carcinoma, medullary thyroid carcinoma, anaplastic carcinoma, and lymphoma are less common thyroid malignancies. Medullary thyroid carcinoma, due to autosomal dominant mutations in the RET protooncogene, arises from the thyroid C cells, which secrete calcitonin. It can occur sporadically or can be inherited in multiple endocrine neoplasia (MEN) type 2 and familial medullary thyroid carcinoma. It is associated with elevated serum calcitonin levels. In affected families, all members should be screened for the mutation, and those identified with the mutation should be treated with prophylactic thyroidectomy in early childhood.
Serum calcium concentration is tightly regulated by the coordinated actions of the parathyroid glands, kidney, liver, and small intestine. Low serum calcium concentrations, detected by calcium-sensing receptors on the surface of parathyroid cells, stimulate parathyroid hormone (PTH) release. PTH in turn promotes release of calcium and phosphorus from bone, reabsorption of calcium from urinary filtrate, and excretion of phosphorus in the urine. Another essential cofactor in calcium homeostasis is 1,25-dihydroxy vitamin D (calcitriol). The first step in production of this active form of vitamin D occurs in the liver where dietary vitamin D is hydroxylated to 25-hydroxy vitamin D. The final step in formation of calcitriol is 1-hydroxylation, which takes place in the kidney under control of PTH. The primary effect of calcitriol is to promote the absorption of calcium from the intestines. In concert with PTH, however, it also facilitates calcium and phosphorus mobilization from bones. Deficiencies or excesses of PTH or calcitriol, abnormalities in their receptors, or abnormalities of vitamin D metabolism lead to clinically significant aberrations in calcium homeostasis. Although calcitonin, released from the thyroid gland C cells, also reduces serum calcium concentration, changes in its serum concentration rarely cause clinically relevant disease.

**HYPOCALCEMIC DISORDERS**

A normal serum calcium concentration is approximately 8.9–10.2 mg/dL. The normal concentration of ionized calcium is approximately 1.1–1.3 mmol/L. Serum calcium levels in newborns, which are slightly lower than in older children and adults, may be as low as 7 mg/dL in premature infants. Fifty to sixty percent of calcium in the serum is protein-bound and metabolically fairly inactive. Thus, measurement of ionized serum calcium, the metabolically active form, is helpful if serum proteins are low or in conditions such as acidosis that cause abnormal calcium binding to protein.

</table>

AHO, Albright hereditary osteodystrophy; APS, autoimmune polyglandular syndrome; PHP, pseudohypoparathyroidism; PPHP, pseudopseudohypoparathyroidism; PTH, parathyroid hormone.

*Urinary calcium excretion (calcium-creatinine ratio) is low in all but familial hypercalciuric hypocalcemia.
The early form of this condition (first 2 weeks of life) occurs in newborns with birth asphyxia. In mothers with hyperparathyroidism, maternal hypercalcemia may suppress fetal PTH secretion and cause early transient neonatal hypoparathyroidism. Likewise, women with gestational diabetes may have relative hyperparathyroidism in the third trimester and their infants may experience transient hypoparathyroidism. Associated hypomagnesemia often aggravates the symptoms associated with hypocalcemia. The late form of neonatal hypoparathyroidism (after 2 weeks of age) occurs in infants receiving high-phosphate formulas (whole cow’s milk is a well-known example). Phosphate binds calcium and produces functional hypocalcemia.

Tumor lysis syndrome and rhabdomyolysis cause cellular destruction that liberates large amounts of intracellular phosphate that complex with serum calcium, producing functional hypocalcemia. Malabsorption states such as celiac disease impair the absorption of calcium, vitamin D, and magnesium, all of which cause hypocalcemia (see Table 34–6). Hypomagnesemia, due to losses from the gastrointestinal tract or kidney, may cause or augment the severity of hypocalcemia by impairing the release of PTH.

Rickets is a term describing the characteristic clinical and bony radiologic features associated with vitamin D deficiency (see Chapter 11). Vitamin D deficiency, caused by lack of sunlight exposure or dietary deficiency, is the most common cause of rickets. Occult vitamin D deficiency is probably more common than is currently recognized. This concern forms the basis for the 2008 recommendation by the American Academy of Pediatrics that breast-fed infants receive vitamin D supplementation of at least 400 IU/d, or supplementation of breast-feeding women with 3–4000 IU/d. Rickets can also be caused by defects in the metabolism of vitamin D (see Table 34–5), including liver disease (impaired 25-hydroxylation), kidney disease (impaired 1-hydroxylation of 25-(OH) vitamin D), genetic deficiency of 1α-hydroxylase (vitamin D–dependent rickets), or end-organ resistance to vitamin D (vitamin D–resistant rickets).

Familial hypophosphatemic rickets has skeletal findings similar to those of vitamin D–related rickets. The defect in this condition is abnormal renal phosphate loss related to abnormal fibroblast growth factor 23 (FGF23) regulation. Dietary deficiency of calcium may also cause rickets but more often causes osteopenia.

Clinical Findings

A. Symptoms and Signs

Prolonged hypocalcemia from any cause is associated with tetany, photophobia, blepharospasm, and diarrhea. The symptoms of tetany are numbness, muscle cramps, twitching of the extremities, carpopedal spasm, and laryngospasm. Tapping the face in front of the ear causes facial spasms (Chvostek sign). Some patients with hypocalcemia exhibit bizarre behavior, irritability, loss of consciousness, and convulsions. Retarded physical and mental development may be present. Headache, vomiting, increased intracranial pressure, and papilledema may occur. In early infancy, respiratory distress may be a presenting finding.

B. Laboratory Findings

In rickets, calcium levels may be low or normal (see Tables 34–5 and 34–6). Phosphate levels in hypocalcemia disorders may be low, normal, or high depending on the cause of the hypocalcemia. Magnesium levels may also be low. PTH levels are reduced in many hypocalcemic conditions, but may be elevated in PHP or severe vitamin D deficiency. Measurement of urinary excretion of calcium as the calcium-creatinine ratio can assist in diagnosis and monitoring of therapy in children on calcitriol therapy.

C. Imaging

Soft tissue and basal ganglia calcification may occur in idiopathic hypoparathyroidism and PHP. Various skeletal changes are associated with rickets, including cupped and irregular long bone metaphyses. Torsional deformities can result in genu varum (bowleg). Accentuation of the costochondral junction gives the rachitic rosary appearance seen on the chest wall.

Differential Diagnosis

Tables 34–5 and 34–6 outline the features of disorders associated with hypocalcemia. In individuals with hypoalbuminemia, the total serum calcium may be low and yet the functional serum ionized calcium is normal. Ionized calcium is the test of choice for hypocalcemia in patients with low serum albumin.

Treatment

A. Acute or Severe Tetany

Hypocalcemia is corrected acutely by administration of intravenous calcium gluconate or calcium chloride; 10 mg/kg is the usual dose in acute treatment. Intravenous calcium infusions should not exceed 50 mg/min because of possible cardiac arrhythmia. Cardiac monitoring should be performed during calcium infusion.

B. Maintenance Management of Hypoparathyroidism or Chronic Hypocalcemia

The objective of treatment is to maintain the serum calcium and phosphate at near-normal levels without excess urinary calcium excretion.

1. Diet—Diet should be high in calcium with added calcium supplements starting at a dose of 50–75 mg of elemental
There are several types of PHP with variable biochemical and phenotypic features (see Table 34–6). Biochemical abnormalities in PHP (hypocalcemia and hyperphosphatemia) are similar to those seen in hypoparathyroidism, but the PTH levels are elevated. PHP may be accompanied by a characteristic phenotype known as Albright hereditary osteodystrophy (AHO), which includes short stature; round, full faces; irregularly shortened fourth metacarpal; a short, thick-set body; delayed and defective dentition; and mild mental retardation. Corneal and lenticular opacities and ectopic calcification of the basal ganglia and subcutaneous tissues (osteoma cutis) may occur with or without abnormal serum calcium levels. Treatment is the same as for hypoparathyroidism.

Pseudopseudohypoparathyroidism (PPHP) describes individuals with the AHO phenotype, but normal calcium homeostasis. PHP and PPHP can occur in the same cohort. Genomic imprinting is probably responsible for the different phenotypic expression of disease. Heterozygous loss of the maternal allele causes PHP and heterozygous loss of the paternal allele causes PPHP.

HYPERCALCEMIC STATES

Hypercalcemia is defined as a serum calcium level > 11 mg/dL. Severe hypercalcemia is a level > 13.5 mg/dL.

- Abdominal pain, polyuria, polydipsia, hypertension, nephrocalcinosis, failure to thrive, renal stones, intractable peptic ulcer, constipation, uremia, and pancreatitis.
- Bone pain or pathologic fractures, subperiosteal bone resorption, renal parenchymal calcification or stones, and osteitis fibrosa cystica.

**PSEUDOHYPOPARATHYROIDISM (RESISTANCE TO PARATHYROID HORMONE ACTION)**

In PHP, PTH production is adequate, but target organs (renal tubule, bone, or both) fail to respond because of receptor resistance. Resistance to PTH action is due to a heterozygous inactivating mutation in the stimulatory G protein subunit associated with the PTH receptor, which leads to impaired signaling. Resistance to other G protein–dependent hormones such as TSH, GHRH, and follicle-stimulating hormone (FSH)/luteinizing hormone (LH), may also be present.
Impaired concentration, altered mental status, mood swings, and coma.

General Considerations

More than 80% of hypercalcemic children or adolescents have either hyperparathyroidism or a malignant tumor. Table 34–7 summarizes the differential diagnosis of childhood hypercalcemia.

Hyperparathyroidism is rare in childhood and may be primary or secondary. The most common cause of primary hyperparathyroidism is parathyroid adenoma. Diffuse parathyroid hyperplasia or multiple adenomas may occur in families. Familial hyperparathyroidism may be an isolated disease, or it may be associated with MEN type 1, or rarely type 2A. Hypercalcemia of malignancy is associated with solid and hematologic malignancies and is due either to local destruction of bone by tumor or to ectopic secretion of PTH-related protein. When ectopic PTH-related protein is present, calcium is elevated, serum PTH is suppressed, and serum PTH–related protein is elevated. Chronic renal disease with impaired phosphate excretion is the most common secondary cause of hyperparathyroidism.

Table 34–7. Hypercalcemic states.

A. Primary hyperparathyroidism
   1. Parathyroid hyperplasia
   2. Parathyroid adenoma
   3. Familial, including MEN types 1 and 2
   4. Ectopic PTH secretion

B. Hypercalcemic states other than primary hyperparathyroidism associated with increased intestinal or renal absorption of calcium
   1. Hypervitaminosis D (including idiopathic hypercalcemia of infancy)
   2. Familial hypocalciuric hypercalcemia
   3. Lithium therapy
   4. Sarcoidosis
   5. Phosphate depletion
   6. Aluminum intoxication

C. Hypercalcemic states other than hyperparathyroidism associated with increased mobilization of bone minerals
   1. Hyperthyroidism
   2. Immobilization
   3. Thiazides
   4. Vitamin A intoxication
   5. Malignant neoplasms
      a. Ectopic PTH secretion or PTH-related protein (PTHrP)
      b. Prostaglandin-secreting tumor and perhaps prostaglandin release from subcutaneous fat necrosis
      c. Tumors metastatic to bone
      d. Myeloma

MEN, multiple endocrine neoplasia; PTH, parathyroid hormone.

Clinical Findings

A. Symptoms and Signs

1. Due to hypercalcemia—Manifestations include hypotonicity and muscle weakness; apathy, mood swings, and bizarre behavior; nausea, vomiting, abdominal pain, constipation, and weight loss; hyperextensibility of joints; and hypertension, cardiac irregularities, bradycardia, and shortening of the QT interval. Coma occurs rarely. Calcium deposits occur in the cornea or conjunctiva (band keratopathy) and are detected by slit-lamp examination. Intractable peptic ulcer and pancreatitis occur in adults but rarely in children.

2. Due to increased calcium and phosphate excretion—Loss of renal concentrating ability causes polyuria, polydipsia, and calcium phosphate deposition in renal parenchyma or as urinary calculi with progressive renal damage.

3. Due to changes in the skeleton—Initial findings include bone pain, osteitis fibrosa cystica, subperiosteal bone absorption in the distal clavicles and phalanges, absence of lamina dura around the teeth, spontaneous fractures, and moth-eaten appearance of the skull on radiographs. Later, there is generalized demineralization with high risk of subperiosteal cortical bone.

B. Imaging

Bone changes may be subtle in children. Technetium sestamibi scintigraphy is preferred over conventional procedures (ultrasound, computed tomography [CT], and MRI) for localizing parathyroid tumors.

Treatment

A. Symptomatic

Initial management is vigorous hydration with normal saline and forced calcium diuresis with a loop diuretic such as furosemide (1 mg/kg given every 6 hours). If response is inadequate, glucocorticoids or calcitonin may be used. Bisphosphonates, standard agents for the management of acute hypercalcemia in adults, are being used more often in refractory pediatric hypercalcemia.
B. Chronic

Treatment options vary with the underlying cause. Resection of parathyroid adenoma or subtotal removal of hyperplastic parathyroid glands is the preferred treatment. Postoperatively, hypocalcemia due to the rapid remineralization of chronically calcium-deprived bones may occur. A diet high in calcium and vitamin D is recommended immediately postoperatively and is continued until serum calcium concentrations are normal and stable. Treatment of secondary hyperparathyroidism from chronic renal disease is primarily directed at controlling serum phosphorus levels with phosphate binders. Pharmacologic doses of calcitriol are used to suppress PTH secretion. Long-term therapy for hypercalcemia of malignancy is the treatment of the underlying disorder.

Course & Prognosis

The prognosis after resection of a single adenoma is excellent. The prognosis following subtotal parathyroidectomy for diffuse hyperplasia or removal of multiple adenomas is usually good and depends on correction of the underlying defect. In patients with multiple sites of parathyroid adenoma or hyperplasia, MEN is likely, and other family members may be at risk. Genetic counseling and DNA analysis to determine the specific gene defect are indicated.

FAMILIAL HYPOCALCIURIC HYPERCALCEMIA
(FAMILIAL BENIGN HYPERCALCEMIA)

Familial hypocalciuric hypercalcemia is distinguished by low to normal urinary calcium excretion as a result of high renal reabsorption of calcium. PTH is normal or slightly elevated. In most cases, the genetic defect is a mutation in the membrane-bound calcium-sensing receptor expressed on parathyroid and renal tubule cells. It is inherited as an autosomal dominant trait with high penetrance. There is a low rate of new mutations. Most patients are asymptomatic, and treatment is unnecessary. A severe form of symptomatic neonatal hyperparathyroidism may occur in infants homozygous for the receptor mutation.

HYPERVITAMINOSIS D

Vitamin D intoxication is almost always the result of ingestion of excessive amounts of vitamin D. Signs, symptoms, and treatment of vitamin D–induced hypercalcemia are the same as those in other hypercalcemic conditions. Treatment depends on the stage of hypercalcemia. Severe hypercalcemia requires hospitalization and aggressive intervention. Due to the storage of vitamin D in the adipose tissue, several months of a low-calcium, low–vitamin D diet may be required.

IDIOPATHIC HYPERCALCEMIA OF INFANCY
(WILLIAMS SYNDROME)

Williams syndrome is an uncommon disorder of infancy characterized by elfin–appearing facies and hypercalcemia in infancy. Other features include failure to thrive, mental and motor retardation, cardiovascular abnormalities (primarily supravalvular aortic stenosis), irritability, purposeless movements, constipation, hypotonia, polyuria, polydipsia, and hypertension. A gregarious and affectionate personality is the rule in children with the syndrome. Hypercalcemia may not appear until several months after birth. Treatment consists of restriction of dietary calcium and vitamin D (Calcilo formula) and, in severe cases, moderate doses of glucocorticoids or even bisphosphonates.

A defect in the metabolism of, or responsiveness to, vitamin D is postulated as the cause of Williams syndrome. Elastin deletions localized to chromosome 7 have been identified in more than 90% of patients. Fluorescent in situ hybridization analysis (FISH) may be the best initial diagnostic tool. The risk of hypercalcemia generally resolves by age 4 and dietary restrictions can be relaxed.

IMMOBILIZATION HYPERCALCEMIA

Abrupt immobilization, particularly in a rapidly growing adolescent, may cause hypercalcemia and hypercalciuria. Abnormalities often appear 1–3 weeks after immobilization. Medical or dietary intervention may be required in severe cases.

HYPOPHOSPHATASIA

Hypophosphatasia is a rare autosomal recessive condition characterized by deficiency of alkaline phosphatase activity in serum, bone, and tissues. Enzyme deficiency leads to poor skeletal mineralization with clinical and radiographic features similar to rickets. Six different clinical forms are identified. The perinatal form is characterized by severe skeletal deformity and death within a few days of birth. The infantile form includes failure to thrive, hypotonia, and craniosynostosis. The childhood form manifests with variable skeletal findings, reduced bone mineral density, and premature loss of deciduous teeth. Serum calcium levels may be elevated. The diagnosis of hypophosphatasia is made by demonstrating elevated urinary phosphoethanolamine associated with low serum alkaline phosphatase. Therapy is generally supportive. Children who survive the neonatal period may experience gradual improvement. Calcitonin may be of value for the acute treatment of hypercalcemia.

GONADS (OVARIES & TESTES)

DEVELOPMENT & PHYSIOLOGY

The fetal gonads develop from bipotential anlagen in the genital ridge. In infants with a Y chromosome, the transcription factor SRY located on the short arm of the Y at location Yp11.3 directs the formation of testes from the bipotential gonads. Without expression of SRY, ovaries develop; however, a 46,XX complement of chromosomes is necessary for the development of normal ovaries. WT1 and many other transcription factors, including but not limited to SF1, DAX1, WNT4, and SOX9, are also important in gonadal differentiation. Two pairs of internal reproductive structures, the müllerian and wolffian ducts, develop in both sexes (Figure 34–6). Once testicular differentiation has been determined, the fetal testes produce two substances critical for male differentiation of these ducts. Antimüllerian hormone (AMH) from the sertoli cells of the testis promotes the regression of müllerian structures, and high local concentrations of testosterone from the Leydig cells stimulate growth of the wolffian structures. These structures become the epididymis, vas deferens, and seminal vesicle. In the absence of testes, as in a XX fetus, the lack of AMH production permits the müllerian structures to develop into the paired fallopian tubes, the midline uterus, and the upper portion of the vagina. The wolffian structures, without exposure to high local concentrations of testosterone, regress.

The external genitalia (Figure 34–7) develop from sexually indifferent structures called the genital tubercle (precursor of the penis or clitoris), the labioscrotal swellings (precursors of the scrotum or labia majora), and the urethral folds (precursors of the penile urethra or labia minora). Normal development of male external genitalia depends on an adequate circulating concentration of testosterone, which is converted to dihydrotestosterone (DHT) in the target tissues by the enzyme 5a-reductase. Sexual differentiation of the external genitalia is completed at about 12 weeks of gestation. Excessive androgen exposure of a female infant prior to this will lead to variable degrees of masculinization of the external genitalia, including posterior labial fusion and formation of penile urethra. Exposure after 12 weeks of gestation will only result in clitoromegaly.

DISORDERS OF SEXUAL DEVELOPMENT

Disorders of sexual development (DSD) is now the preferred terminology replacing terms such as “intersex” and “pseudohermaphrodite,” as these contain pejorative elements. DSD result from incomplete or disordered genital or gonadal development that causes a discordance between genetic sex, gonadal sex, and phenotypic sex. When an infant is born with genital ambiguity, immediate consultation with pediatric endocrinology, urology, and, if possible, psychiatry/psychology and genetics is required. Disorders of sexual development stem from alterations in three main processes: gonadal differentiation, steroidogenesis, or androgen action.

1. Disorders of Gonadal Differentiation

These abnormalities include XY gonadal dysgenesis, mosaicism involving the Y chromosome, XX sex reversal, and true hermaphroditism. Gonadal dysgenesis occurs as a result of abnormal gonadal development. Individuals with complete 46,XY gonadal dysgenesis have streak gonads that do not produce AMH or testosterone. Therefore, external genitalia and internal reproductive structures in complete gonadal dysgenesis are normal female external genitalia. Affected individuals typically present as girls with delayed puberty and amenorrhea. Partial XY gonadal dysgenesis is associated with incomplete testis development resulting in a phenotype of varying degrees of virilization. Mutations in the transcription factors SRY, WT1, SF1, and SOX9 have all been implicated in 46,XY gonadal dysgenesis. It is important...
to recognize that some of these mutations are associated with abnormalities separate from sexual development. For example, WTI mutations are associated with increased risk of Wilms tumor and nephropathy.

Mosaicism occurs when cells with two or more karyotypes are found in the same individual. The most common form of mosaicism is 45,X/46,XY. The majority of these individuals have normal male external genitalia but some may have ambiguity due to abnormal testicular formation. These individuals may also share some features of Turner syndrome such as short stature. XX sex reversal, characterized by masculine or ambiguous genital development in an XX individual, can be caused by translocation of the SRY gene to the X chromosome. A true hermaphrodite is defined as having both ovarian and testicular tissue and most often has a karyotype of 46,XX. Dysgenetic gonads have an increased risk for neoplastic transformation; therefore, if gonads are intra-abdominally located and cannot be brought down to the scrotum, gonadectomy is recommended.

2. Disorders of Steroidogenesis (Figure 34-8)

Testosterone biosynthesis in the testicular leydig cells depends on the function of multiple enzymes which are responsible for conversion of intermediary metabolites. Enzymatic defects in this pathway result in decreased or
absent testosterone synthesis and in affected XY individuals, there will be reduced or lack of virilization of the external genitalia. Wolffian duct derivatives can be absent, hypoplastic, or normal depending on the degree of the enzyme inactivity. Sertoli cell production of AMH is preserved so müllerian development is also inhibited. Disorders in this category include StAR deficiency, 3β-hydroxysteroid dehydrogenase deficiency, 17α-hydroxylase/17,20 lyase deficiency, and 17β-hydroxysteroid dehydrogenase deficiency. Additionally, defects in conversion of testosterone to dihydrotestosterone (DHT) from 5α-reductase deficiency also results in undervirilization. In this disorder, there is a deficiency of the type 2 isoenzyme of 5α-reductase, which is the primary isoenzyme present in the fetus. The type 1 isoenzyme becomes expressed at puberty at that time more DHT is produced and will masculinize the external genitalia. Since the gonads and adrenal gland share common enzymes of steroid hormone production, some of the enzymatic defects associated with male undervirilization may also affect production of cortisol and aldosterone, leading to cortisol deficiency and salt wasting (see later section on the Adrenal Cortex).

In an XX individual, the most common disorder in this category is congenital adrenal hyperplasia (CAH) secondary to 21-hydroxylase deficiency. In the classic salt-losing form of this disorder, infant girls present with genital ambiguity but have normal uterus and ovaries. A less common form of CAH is 3β-hydroxysteroid dehydrogenase deficiency, which presents in the same manner.

3. Disorders of Androgen Action

Androgen Insensitivity Syndrome (AIS) is caused by a mutation in the androgen receptor gene located on the proximal, long arm of the X chromosome at Xq11–12. In complete androgen insensitivity syndrome (CAIS), there is no androgen action; thus, 46,XY affected individuals have female external genitalia with a short, blind-ending vagina. The production of AMH in these individuals leads to müllerian regression and the absence of testosterone action leads
to absent or rudimentary wolffian structures. Gonads are located either intra-abdominally or in the inguinal canal. Some of these individuals present when surgery for an inguinal hernia reveals testis in the hernia sack. With partial androgen insensitivity syndrome (PAIS), the degree of virilization and ambiguity depends on the degree of abnormality in androgen binding.

4. Evaluation

A complete family and maternal history should be completed focusing on previous affected offspring, neonatal deaths, history of consanguinity, and maternal exposure to any drugs or hormones. On physical examination, dysmorphic features, other congenital anomalies, and hyperpigmentation of nipples and labia/scrotum should be noted. The genital examination should include measuring the width and length of the stretched phallus and noting the position of the urethral meatus. The normal stretched penile length (SPL) is greater than 2.5 cm (and diameter greater than 0.9 cm) in term infants, greater than 2 cm in 34-week infants, greater than 1.5 cm in 30-week infants, and greater than 0.8 cm in 25-week infants. The labioscrotal and inguinal regions should be palpated for presence of gonads. Since ovaries and streak gonads do not typically descend, the presence of a palpable gonad is suggestive of a 46,XY or 45X/46,XY karyotype. The labioscrotal area should also be evaluated for the degree of fusion and rugation.

In all infants, karyotype, FISH for SRY, electrolytes, LH, FSH, and testosterone should be done initially. Additional laboratory evaluation is usually based on these results. A pelvic ultrasound can be helpful to evaluate for the presence of a uterus; however, ultrasound findings can be unreliable so should be done in an institution which has expertise in pediatric imaging. Many times, laparoscopic examination is necessary to delineate internal structures. If the karyotype is 46,XX, a 17-hydroxyprogesterone level should be sent as the most common diagnosis will be congenital adrenal hyperplasia due to 21-hydroxylase deficiency. If the karyotype is 46,XY, then tests to evaluate for disorders of testicular development, steroidogenesis, and androgen action are recommended. It is important that gender assignment be avoided until expert evaluation by a multidisciplinary team is performed. The team should develop a plan for diagnosis, gender assignment, and treatment options before making any recommendations. Open communications with the parents is essential and their participation in decision making encouraged.

**Table 34–8. Causes of precocious pubertal development.**

| A. Central (GnRH-dependent) precocious puberty |
| 1. Idiopathic |
| 2. Central nervous system abnormalities |
| a. Acquired—abscess, chemotherapy, radiation, surgical trauma |
| b. Congenital—arachnoid cyst, hydrocephalus, hypothalamic hamartoma, septo-optic dysplasia, suprasellar cyst |
| c. Tumors—astrocytoma, craniopharyngioma, glioma |
| B. Peripheral (GnRH-independent) precocious puberty |

that of normal puberty. Central precocious puberty in girls is generally idiopathic but may be secondary to a central nervous system (CNS) abnormality that disrupts the prepubertal restraint on the GnRH pulse generator. Such CNS abnormalities include, but are not limited to, hypothalamic hamartomas, CNS tumors, cranial irradiation, hydrocephalus, and trauma. Peripheral precocious puberty (GnRH-independent) occurs independent of gonadotropin secretion. In girls, peripheral precocious puberty can be caused by ovarian or adrenal tumors, ovarian cysts, congenital adrenal hyperplasia, McCune-Albright syndrome, or exposure to exogenous estrogen. Estrogen-secreting ovarian or adrenal tumors are rare. Girls with these tumors typically present with markedly elevated estrogen levels and rapidly progressive pubertal changes. McCune-Albright syndrome is a triad of irregular café au lait lesions, polyostotic fibrous dysplasia, and GnRH-independent precocious puberty. It is caused by an activating mutation in the gene encoding the α-subunit of Gs, the G protein that stimulates adenyl cyclase. Endocrine cells with this mutation have autonomous hyperfunction and secrete excess amounts of their respective hormones.

**Clinical Findings**

**A. Symptoms and Signs**

Female central precocious puberty usually starts with breast development, followed by pubic hair growth and menarche. However, the order may vary and girls less than 5 years of age may not have pubic hair development. Girls with ovarian cysts or tumors generally have signs of estrogen excess such as breast development and possibly vaginal bleeding. Adrenal tumors or CAH produce signs of adrenarche (ie, pubic hair, axillary hair, acne, and sometimes, increased body odor). Children with precocious puberty usually have accelerated growth and skeletal maturation, and may temporarily be tall for age. However, because skeletal maturation advances at a more rapid rate than linear growth, final adult stature may be compromised.

**B. Laboratory Findings**

One of the first steps in evaluating a child with early pubertal development is obtaining a radiograph of the left hand and wrist to determine skeletal maturity (bone age). An estradiol level can also be drawn to rule out an ovarian tumor or cyst. If the bone age is advanced, further evaluation is warranted. In central precocious puberty, the basal serum concentrations of FSH and LH may still be in the prepubertal range. Thus, documentation of the maturity of the hypothalamic-pituitary axis depends on demonstrating a pubertal LH response after stimulation with a GnRH agonist. In peripheral precocious puberty, basal serum FSH and LH are low, and the LH response to GnRH stimulation is suppressed by feedback inhibition of the hypothalamic-pituitary axis by the autonomously secreted gonadal steroids (see Figure 34–1).

In girls with an ovarian cyst or tumor, estradiol levels will be markedly elevated. In girls with signs of adrenarche and an advanced bone age, androgen levels (testosterone, androstenedione, dehydroepiandrosterone-sulfate) and possibly adrenal intermediate metabolites (such as 17-hydroxyprogesterone) should be measured.

**C. Imaging**

When a diagnosis of central precocious puberty is made, a MRI of the brain should be done to evaluate for CNS lesions. It is unlikely that an abnormality will be found in girls 6–8 years of age, so the need for an MRI in this age group should be individually assessed. In girls whose laboratory tests suggest peripheral precocious puberty, an ultrasound of the ovaries and adrenal gland is indicated.

**Treatment**

Girls with central precocious puberty can be treated with GnRH analogues that downregulate pituitary GnRH receptors and thus decrease gonadotropin secretion. Currently, the two most common GnRH analogues used are (1) leuprolide, which is given as a monthly intramuscular injection or (2) histrelin subdermal implant, which is replaced annually. With treatment, physical changes of puberty regress or cease to progress and linear growth slows to a prepubertal rate. Projected final heights often increase as a result of slowing of skeletal maturation. After stopping therapy, pubertal progression resumes, and ovulation and pregnancy have been documented. Therapy is instituted for both psychosocial and final height considerations.

Treatment of peripheral precocious puberty is dependent on the underlying cause. In a girl with an ovarian cyst, intervention is generally not necessary, as the cyst usually regresses spontaneously. Serial ultrasounds are recommended to document this regression. Treatment with glucocorticoids is indicated for congenital adrenal hyperplasia. Surgical resection is indicated for the rare adrenal or ovarian tumor.

In McCune-Albright syndrome, therapy with antiestrogens (eg, tamoxifen), agents that block estrogen synthesis (ketoconazole), or aromatase inhibitors (eg, letrozole) may be effective. Regardless of the cause of precocious puberty or the medical therapy selected, attention to the psychological needs of the patient and family is essential.

**2. Benign Variants of Precocious Puberty**

Benign premature thelarche (benign early breast development) occurs most commonly in girls younger than 2 years of age. Girls present with isolated breast development without other signs of puberty such as linear growth acceleration and pubic hair development. The breast development is typically
present since birth and often waxes and wanes in size. It may be unilateral or bilateral. Benign thelarche is thought to be caused by greater ovarian hormone production during infancy. Treatment is parental reassurance regarding the self-limited nature of the condition. Observation of the child every few months is also indicated. Onset of thelarche after age 36 months or in association with other signs of puberty requires evaluation.

Benign premature adrenarche (benign early adrenal maturation) is manifested by early development of pubic hair, axillary hair, acne, and/or body odor. Benign premature adrenarche is characterized by normal linear growth and no or minimal bone age advancement. The timing of true puberty is not affected, and no treatment is required. Approximately 15% of girls with premature adrenarche are at risk for developing polycystic ovarian syndrome during puberty.

### 3. Delayed Puberty

Delayed puberty in girls should be evaluated if there are no pubertal signs by age 13 years or menarche by 16 years. Failure to complete pubertal development to Tanner stage V within 4 years of onset is also considered delay. Primary amenorrhea refers to the absence of menarche, and secondary amenorrhea refers to the absence of menses for at least 6 months after regular menses have been established. The most common cause of delayed puberty is constitutional growth delay (Table 34–9). This growth pattern, characterized by short stature, normal growth velocity, and a delay in skeletal maturation, is described in detail earlier in this chapter. The timing of puberty is commensurate to the bone age, not the chronologic age. Girls may also have delayed puberty from any condition that delays growth and skeletal maturation, such as hypothyroidism and GHD.

Primary hypogonadism in girls refers to a primary abnormality of the ovaries. The most common diagnosis in this category is Turner syndrome, in which the lack of or an abnormal second X chromosome leads to early loss of oocytes and accelerated stromal fibrosis. Other types of primary ovarian insufficiency are less common, including 46,XY gonadal dysgenesis, 46,XX gonadal dysgenesis, galactosemia, and autoimmune ovarian failure. Radiation and chemotherapy can also cause primary ovarian insufficiency. Girls who are premutation carriers for fragile X syndrome are also at increased risk of premature ovarian failure.

Central hypogonadism refers to a hypothalamic or pituitary deficiency of GnRH or FSH/LH, respectively. Central hypogonadism can be functional (reversible), caused by stress, undernutrition, prolactinemia, excessive exercise, or chronic illness. Permanent central hypogonadism is typically associated with conditions that cause multiple pituitary hormone deficiencies, such as congenital hypopituitarism, CNS tumors, or cranial irradiation. Isolated gonadotropin deficiency is rare but may occur in Kallmann syndrome, which is also characterized by hyposmia or anosmia. There are many genes that have been implicated in both isolated gonadotropin deficiency and Kallmann syndrome. In either primary or central hypogonadism, signs of adrenarche are generally present.

Delayed menarche or secondary amenorrhea may result from primary ovarian failure or central hypogonadism, or may be the consequence of hyperandrogenism, anatomic obstruction precluding menstrual outflow, or müllerian agenesis. This latter disorder is called Mayer-Rokitansky-Küster-Hauser syndrome and is characterized by an absent vagina and various uterine abnormalities, with or without renal and skeletal anomalies.

Girls with complete AIS (androgen receptor defect) typically present with primary amenorrhea, breast development, and absence of sexual hair. The affected individual (46,XY) has functioning testes that produce antimüllerian hormone during fetal life. Thus, no müllerian duct (oviduct or uterus) development occurs. External genitalia are female because of the lack of androgen action. At puberty, if the gonads have not been removed, testosterone produced

**Clinical Evaluation**

The history should ascertain whether and when puberty commenced, level of exercise, nutritional intake, stressors, sense of smell, symptoms of chronic illness, and family history of delayed puberty. Past growth records should be assessed to determine if height and weight velocity have been appropriate. Physical examination includes body proportions, breast and genital development, and stigmata of Turner syndrome. Pelvic examination or pelvic ultrasonography should be considered, especially in girls with primary amenorrhea.

A bone age radiograph should be obtained first. If the bone age is lower than that consistent with pubertal onset (<12 years in girls), evaluations should focus on finding the cause of the bone age delay. If short stature and normal growth velocity are present, constitutional growth delay is likely. If growth rate is abnormal, laboratory studies may include a complete blood count, erythrocyte sedimentation rate, chemistry panel, and renal and liver function tests to look for unsuspected chronic medical illness. Evaluation for hypothyroidism and GHD may also be indicated. Measurement of FSH and LH may not be helpful in the setting of delayed bone age since prepubertal levels are normally low. Determination of a karyotype should be considered if there is short stature, or any stigmata of Turner syndrome.

If the patient has attained a bone age of more than 12 years and there are minimal or no signs of puberty on physical examination, FSH and LH levels will distinguish between primary ovarian failure and central hypogonadism. Primary ovarian failure is also called hypergonadotropic hypogonadism, as there is lack of estrogen feedback to the brain with elevated FSH and LH. If gonadotropins are elevated, a karyotype is the next step, as Turner syndrome is the most common cause of female hypergonadotropic hypogonadism. Central hypogonadism is characterized by low gonadotropin levels, and evaluation is geared toward determining if the hypogonadism is functional or permanent. Laboratory tests should be directed toward identifying chronic disease and hyperprolactinemia. Cranial MRI may be helpful.

In girls with adequate breast development and amenorrhea, a progesterone challenge may be helpful to determine if sufficient estrogen is being produced. Girls who are producing estrogen have a withdrawal bleed after 5–10 days of oral progesterone, whereas those who are estrogen-deficient have little or no bleeding. The exception is girls with an absent uterus (androgen insensitivity or Mayer-Rokitansky-Küster-Hauser syndrome). They have sufficient estrogen but cannot have withdrawal bleeding. The most common cause of amenorrhea in girls with sufficient estrogen is polycystic ovarian syndrome. Girls who are estrogen-deficient should be evaluated similarly to those who have delayed puberty.

**Treatment**

Replacement therapy in hypogonadal girls begins with estrogen alone at the lowest available dosage. Oral preparations such as estradiol or topical patches are used. Cyclic estrogen–progesterone therapy is started 12–18 months later, and eventually the patient may be switched over to a birth control pill for convenience. Progesterone therapy is needed to counteract the effects of estrogen on the uterus, as unopposed estrogen promotes endometrial hyperplasia. Estrogen is also necessary to promote bone mineralization and prevent osteoporosis.

4. Secondary Amenorrhea

See discussion of amenorrhea in Chapter 4.

**ABNORMALITIES IN MALE PUBERTAL DEVELOPMENT & TESTICULAR FUNCTION**

1. Precocious Puberty in Boys

Puberty is considered precocious in boys if secondary sexual characteristics appear before age 9 years. While the frequency of central precocious puberty is much lower in boys than girls, boys are more likely to have an associated CNS abnormality (see Table 34–8).

Several types of gonadotropin-independent (peripheral) precocious puberty occur in boys (see Table 34–8). Increased adrenal androgen production from an adrenal tumor or from a virilizing form of CAH will cause pubertal changes in boys. Familial male-limited gonadotropin-independent puberty (familial testotoxicosis) is a condition in which a mutated LH receptor on the Leydig cell is autonomously activated, resulting in testicular production of testosterone despite prepubertal LH levels. McCune-Albright syndrome can also occur in boys. Leydig cell tumors of the testis cause rapid onset of unilateral testicular enlargement and physical signs of testosterone excess. Human chorionic gonadotropin (HCG)–secreting tumors such as teratomas, CNS germinomas, and hepatoblastomas also cause early puberty in boys, as HCG stimulates testosterone production from Leydig cells.

**Clinical Findings**

**A. Symptoms and Signs**

In precocious development, increased linear growth rate and growth of pubic hair are the most common presenting signs. Testicular size may differentiate central precocity, in
which the testes enlarge, from gonadotropin-independent causes such as CAH, in which the testes usually remain small (< 2 cm in the longitudinal axis). However, in familial testotoxicosis and HCG-mediated precocious puberty, there is some testicular enlargement but not to the degree as seen in central precocity. Tumors of the testis are associated with either asymmetrical or unilateral testicular enlargement.

### B. Laboratory Findings

Elevated testosterone levels verify early pubertal status but do not differentiate the source. As in girls, basal serum LH and FSH concentrations may not be in the pubertal range in boys with central precocious puberty, but the LH response to GnRH stimulation testing is pubertal. Sexual precocity caused by CAH is usually associated with abnormal plasma dehydroepiandrosterone, androstenedione, 17-hydroxyprogesterone (in CAH due to 21-hydroxylase deficiency), 11-deoxycortisol (in CAH due to 11-hydroxylase deficiency), or a combination of these steroids (see the section Adrenal Cortex, later). Serum β-HCG concentrations can signify the presence of an HCG-producing tumor (eg, CNS dysgerminoma or hepatoma) in boys who present with precocious puberty and testicular enlargement but suppressed gonadotropins following GnRH testing.

### C. Imaging

In all boys with central precocious puberty, cranial MRI should be obtained to evaluate for a CNS abnormality. If testing suggests peripheral precocious puberty, and laboratory studies are not consistent with CAH, ultrasonography may be useful in detecting hepatic, adrenal, and testicular tumors.

### Treatment

Treatment of central precocious puberty in boys is with GnRH analogues, similar to treatment in girls. Boys with McCune-Albright syndrome or familial testotoxicosis can be treated with agents that block steroid synthesis (ketoconazole), or with a combination of antiandrogens (spironolactone) and aromatase inhibitors (anastrozole or letrozole) which block the conversion of testosterone to estrogen.

### 2. Delayed Puberty

Boys should be evaluated for delayed puberty if they have no secondary sexual characteristics by 14 years of age or if more than 5 years have elapsed since the first signs of puberty without completion of genital growth.

The most common cause of delayed puberty in boys, as in girls, is constitutional growth delay, a normal variant of growth that is described in detail earlier in this chapter. Hypogonadism in boys may be primary, due to absence, malfunction, or destruction of testicular tissue, or central, due to pituitary or hypothalamic insufficiency. Primary testicular insufficiency may be due to anorchia, Klinefelter syndrome (47,XXY), or other sex chromosome abnormalities, enzymatic defects in testosterone synthesis, or inflammation or destruction of the testes following infection (mumps), autoimmune disorders, radiation, trauma, or tumor.

Central hypogonadism may accompany panhypopituitarism, Kallmann syndrome (GnRH deficiency with anosmia), or isolated LH or FSH deficiencies. Destructive lesions in or near the anterior pituitary (especially craniopharyngioma and glioma) or infection may also result in hypothalamic or pituitary dysfunction. Prader-Willi syndrome and Laurence-Moon syndrome (Bardet-Biedl syndrome) are frequently associated with LH and FSH deficiency in boys and girls secondary to GnRH deficiency. Deficiencies in gonadotropins may be partial or complete. Functional or reversible gonadotropin may occur with chronic illness, malnutrition, hyperprolactinemia, hypothyroidism, or excessive exercise.

#### Clinical Evaluation

The history should focus on whether and when puberty has started, testicular descent, symptoms of chronic illness, nutritional intake, sense of smell, and family history of delayed puberty. Physical examination should include body proportions, height and weight, pubertal stage, and testicular location, size, and consistency. Testes less than 2 cm in length are prepubertal; testes more than 2.5 cm in length suggest early pubertal growth.

A radiograph of the left hand and wrist to assess bone age should be the first step in evaluating a boy with delayed puberty. If bone age is delayed (< 12 years) and growth velocity is normal, constitutional growth delay is the most likely diagnosis. Laboratory evaluation includes LH and FSH levels (especially if bone age is > 12 years). Elevated gonadotropin levels indicate primary hypogonadism or testicular failure. The most common cause of primary hypogonadism in boys is Klinefelter syndrome; however, the usual presentation of this disorder is not delayed puberty but failure to complete puberty with a discrepancy noted between testicular size (small) and degree of virilization. If gonadotropin values are low, the working diagnosis is central hypogonadism and further evaluation should focus on looking for pituitary hormone deficiencies, chronic disease or undernutrition (or both), hyperprolactinemia, and CNS abnormalities.

#### Treatment

Boys with simple constitutional delay may be offered a short (4–6 months) course of low-dose depot testosterone (50–75 mg/mo) to stimulate their pubertal appearance and “jump-start” their endogenous development. In adolescents with permanent hypogonadism, treatment with depot testosterone, beginning with 50–75 mg intramuscularly each month, may be used until growth is complete. Thereafter, adult dosing (150–200 mg every 2–3 weeks) may be used.
An alternative to intramuscular injections is testosterone gel, either in single-dose packets or in a pump set to dispense a preset dose. Gel is applied daily after showering. Specific therapy for GnRH deficiency with pulsatile subcutaneous GnRH may promote fertility in patients with hypothalamic-pituitary insufficiency. However, the inconvenience of treatment and the need for repeated doses for long periods of time have limited its application in pediatrics.

3. Cryptorchidism

Cryptorchidism (undescended testis) is very common, affecting 2%–4% of full-term male newborns and up to 30% of premature infants. Short-term postnatal endogenous testosterone secretion decreases the incidence of cryptorchidism to 1% by 3 months of age. After 6 months of age, spontaneous descent occurs only very rarely. Consequently, intervention is typically considered beginning at this time.

Infertility and testicular malignancy are major risks of cryptorchidism. Fertility is impaired by approximately 33% after unilateral cryptorchidism and by 66% after bilateral disease. The cancer risk for adults after cryptorchidism in childhood is reported to be 5–10 times greater than normal. However, histologic changes clearly occur as early as age 6 months in children with undescended testes.

The cause of most cases of cryptorchidism is not completely understood. Cryptorchidism can occur in an isolated fashion or associated with other findings. Abnormalities in the hypothalamic-pituitary-gonadal axis predispose to cryptorchidism. Androgen biosynthesis or receptor defects also predispose to cryptorchidism and undervirilization.

The diagnosis of bilateral cryptorchidism in an apparently normal male newborn should never be made until the possibility that the child is actually a fully virilized female with potentially fatal salt-losing CAH has been considered.

Clinical Findings

In infants between 2 and 6 months of age, LH, FSH, and testosterone levels help determine whether testes are present. After this time, an HCG stimulation test can be done to confirm the presence or absence of functional abdominal testes. Ultrasonography, CT scanning, and MRI may detect testes in the inguinal region, but these studies are not completely reliable in finding abdominal testes.

Differential Diagnosis

In palpating the testis, the cremasteric reflex that causes the testis to retract into the inguinal canal or abdomen (pseudocryptorchidism) may be elicited. To prevent retraction during examination, the fingers first should be placed across the abdominal ring and the upper portion of the inguinal canal to obstruct testicular ascent. Examination while the child is in the squatting position or in a warm bath is helpful.

No treatment for retractile testes is necessary, and the prognosis for testicular descent and function is excellent.

Treatment

The current recommendation for treatment of cryptorchidism is that surgical orchidopexy be performed by an experienced surgeon if descent has not occurred by 6–12 months of age. The recommended timing of surgical intervention is based on the assumption that early surgery to relocate the testis into the low-temperature environment of the scrotum will allow normal germ cell development and decrease the risk for future infertility and cancer. However, in a certain number of cases, there is a primary abnormality of the testis which is thought to be responsible for the undescend and future risks. Hormonal therapy with HCG to induce descent of the testis only has a success rate of about 20%, and even less when retractile testes are excluded. HCG doses range from 250 to 1000 international units and are given twice weekly for 5 weeks. In the future, there may be a role for therapy with a GnRH analogue in addition to surgery as preliminary studies suggest that this treatment stimulates germ cell development and thus may improve future fertility.

4. Gynecomastia

Gynecomastia is a common, self-limited condition that may occur in up to 75% of normal pubertal boys. Adolescent gynecomastia typically resolves within 2 years but may not totally resolve if the degree of gynecomastia is extreme (> 2 cm of tissue). Gynecomastia may sometimes occur as part of Klinefelter syndrome, or it may occur in boys who are taking drugs such as antidepressants or marijuana. Medical therapy using antiestrogens and aromatase inhibitors have been used but generally the results are not deemed satisfactory. Surgical intervention is a reasonable option for prolonged and/or severe cases (see Chapter 4).
fasciculata makes cortisol and small amounts of mineralocorticoids. The innermost zona reticularis produces mainly androgens and estrogens. A fetal zone, or provisional cortex, that predominates during fetal development, produces glucocorticoids, mineralocorticoids, androgens, and estrogens. The fetal zone is relatively deficient in 3β-hydroxysteroid dehydrogenase (see Figure 34–8); hence placentally produced progesterone is the major precursor used in fetal adrenal production of cortisol and aldosterone.

The adrenal cortical production of cortisol is under the control of pituitary adrenocorticotropic hormone (ACTH; see Figure 34–1 and Table 34–1), which is in turn regulated by the hypothalamic peptide, corticotropin-releasing hormone (CRH). The complex interaction of CNS influences on CRH secretion, coupled with negative feedback of serum cortisol, leads to a diurnal pattern of ACTH and cortisol release. ACTH concentration is greatest during the early morning hours with a smaller peak in the late afternoon and a nadir at night. The pattern of serum cortisol concentration follows this pattern with a lag of a few hours. In the absence of cortisol feedback, there is dramatic CRH and ACTH hypersecretion.

Glucocorticoids are critical for gene expression in a many cell types. In excess, glucocorticoids are both catabolic and anabolic; that is, they promote the release of amino acids from muscle and increase gluconeogenesis while decreasing incorporation of amino acids into muscle protein. They also antagonize insulin activity and facilitate lipolysis. Glucocorticoids help maintain blood pressure by promoting peripheral vascular tone and sodium and water retention.

Mineralocorticoids (primarily aldosterone in humans) promote sodium retention and stimulate potassium excretion in the distal renal tubule. Although ACTH can stimulate aldosterone production, the predominant regulator of aldosterone secretion is the volume- and sodium-sensitive renin-angiotensin-aldosterone system. Elevations of serum potassium also directly influence aldosterone release from the cortex.

Androgens (dehydroepiandrosterone and androstenedione) production by the zona reticularis is insignificant before puberty. At the onset of puberty, androgen production increases and may be an important factor in the dynamics of puberty in both sexes. The adrenal gland is a major source of androgen in the pubertal and adult female.

### ADRENOCORTICAL INSUFFICIENCY (ADRENAL CRISIS, ADDISON DISEASE)

The leading causes of adrenal insufficiency are hereditary enzyme defects (congenital adrenal hyperplasia), autoimmune destruction of the glands (Addison disease), central adrenal insufficiency caused by intracranial neoplasm or its treatment, or congenital midline defects associated with optic nerve hypoplasia (septo-optic dysplasia). Rare forms of familial adrenal insufficiency occur in association with cerebral sclerosis and spastic paraplegia (adrenoleukodystrophy) or in association with achalasia and alacrimia in the triple A syndrome or Allgrove syndrome. Addison disease may be familial and has been described in association with hypoparathyroidism, mucocutaneous candidiasis, hypothyroidism, pernicious anemia, hypogonadism, and diabetes mellitus as one of the polyglandular autoimmune syndromes. Less commonly, the gland is destroyed by tumor, calcification, or hemorrhage (Waterhouse-Friderichsen syndrome). Adrenal disease secondary to opportunistic infections (fungal or tuberculous) is reported in AIDS. In children, central adrenal insufficiency due to anterior pituitary tumor is rare. Salt-losing disorders can occur from homozygous mutations affecting the aldosterone synthase enzyme (CYP11B2) or from partial or complete unresponsiveness of the mineralocorticoid receptor to aldosterone action (pseudoaldosteronism). A transient autosomal dominant form of pseudoaldosteronism has been reported in infancy. It is speculated to be secondary to a maturation disorder of function or number of aldosterone receptors and usually resolves by the first year of life.

Acute illness, surgery, trauma, or hyperthermia may precipitate an adrenal crisis in patients with adrenal insufficiency. Patients with primary adrenal insufficiency are at greater risk for life-threatening crisis than patients with central ACTH deficiency because mineralocorticoid secretion and low-level autonomous cortisol secretion remain intact in central ACTH deficiency.

#### Clinical Findings

**A. Symptoms and Signs**

1. **Acute form (adrenal crisis)**—Manifestations include nausea, vomiting, diarrhea, abdominal pain, dehydration, fever (sometimes followed by hypothermia), weakness, hypotension, circulatory collapse, confusion, and coma. Increased pigmentation may be associated with primary adrenal insufficiency caused by melanocyte-stimulating activity of the hypersecreted parent molecule of ACTH, pro-opiomelanocortin.

2. **Chronic form**—Manifestations include fatigue, hypotension, weakness, failure to gain weight, weight loss, salt craving (primary insufficiency), vomiting, and dehydration. Diffuse tanning with increased pigmentation over pressure points, scars, and mucous membranes may be present in primary adrenal insufficiency. A small heart may be seen on chest radiograph.

**B. Laboratory Findings**

1. **Suggestive of adrenocortical insufficiency**—In primary adrenal insufficiency, serum sodium and bicarbonate levels, arterial partial pressure of carbon dioxide, blood pH, and blood volume are decreased. Serum potassium and urea nitrogen levels are increased. Urinary sodium level and the
ratio of urinary sodium to potassium are inappropriate for the degree of hyponatremia. In central adrenal insufficiency, serum sodium levels may be mildly decreased as a result of impaired water excretion. Eosinophilia and moderate lymphopenia occur in both forms of insufficiency.

2. Confirmatory tests

A. ACTH (cosyntropin) stimulation test—In primary adrenal insufficiency (originating in the gland itself), plasma cortisol and aldosterone concentrations do not increase significantly over baseline 60 minutes after an intravenous dose of ACTH (250 mcg). To diagnose central adrenal insufficiency, a low dose of ACTH is given (1 mcg).

B. Baseline serum ACTH concentration—Values are elevated in primary adrenal failure and low in central adrenal insufficiency.

C. Urinary free cortisol—Values are decreased.

D. CRH test—This test assesses responsiveness of the entire hypothalamic-pituitary-adrenal axis. After administration of ovine CRH, serum concentrations of ACTH and cortisol are measured over 2 hours. Verification of an intact axis or localization of the site of impairment is possible with careful interpretation of results.

Differential Diagnosis

Acute adrenal insufficiency must be differentiated from severe acute infections, diabetic coma, various disturbances of the CNS, and acute poisoning. In the neonatal period, adrenal insufficiency may be clinically indistinguishable from respiratory distress, intracranial hemorrhage, or sepsis. Chronic adrenocortical insufficiency must be differentiated from anorexia nervosa, certain muscular disorders (myasthenia gravis), salt-losing nephritis, and chronic debilitating infections, and must be considered in cases of recurrent spontaneous hypoglycemia.

Treatment

A. Acute Insufficiency (Adrenal Crisis)

1. Hydrocortisone sodium succinate—Hydrocortisone sodium succinate is given initially at a dose of 50 mg/m² intravenously over 2–5 minutes or intramuscularly; thereafter, it is given intravenously, 12.5 mg/m², every 4–6 hours until stabilization is achieved and oral therapy can be tolerated.

2. Fluids and electrolytes—In primary adrenal insufficiency, 5%–10% glucose in normal saline, 10–20 mL/kg intravenously, is given over the first hour and repeated if necessary to reestablish vascular volume. Normal saline is continued thereafter at 1.5–2 times the maintenance fluid requirements. Intravenous boluses of glucose (10% glucose, 2 mL/kg) may be needed every 4–6 hours to treat hypoglycemia. In central adrenal insufficiency, routine fluid management is generally adequate after restoration of vascular volume and institution of cortisol replacement.

3. Fludrocortisone—When oral intake is tolerated, fludrocortisone, 0.05–0.15 mg daily, is started and continued as necessary every 12–24 hours for primary adrenal insufficiency.

4. Inotropic agents—Rarely, inotropic agents such as dopamine and dobutamine are needed. However, adequate cortisol replacement is critical because pressor agents may be ineffective in adrenal insufficiency.

5. Waterhouse-Friderichsen syndrome with fulminant infections—The use of adrenocorticosteroids and norepinephrine in the treatment or prophylaxis of fulminant infections remains controversial. Corticosteroids may augment the generalized Shwartzman reaction in fatal cases of meningococcemia. However, corticosteroids should be considered if there is possible adrenal insufficiency, particularly if there is hypotension and circulatory collapse.

B. Maintenance Therapy

Following initial stabilization, the most effective substitution therapy is hydrocortisone, combined with fludrocortisone in primary adrenal insufficiency. Overtreatment should be avoided as it causes obesity, growth retardation, and other cushingoid features. Additional hydrocortisone, fludrocortisone, or sodium chloride, singly or in combination, may be necessary with acute illness, surgery, trauma, or other stress reactions. Supportive adrenocortical therapy should be given whenever surgical operations are performed in patients who have at some time received prolonged therapy with adrenocorticosteroids.

1. Glucocorticoids—A maintenance dosage of 6–10 mg/m²/d of hydrocortisone (or equivalent) is given orally in two or three divided doses. The dosage of all glucocorticoids is increased to 30–50 mg/m²/d during intercurrent illnesses or other times of stress.

2. Mineralocorticoids—In primary adrenal insufficiency, fludrocortisone is given, 0.05–0.15 mg orally daily as a single dose or in two divided doses. Periodic monitoring of blood pressure is recommended to avoid overdosing.

3. Salt—The child should be given ready access to table salt. Frequent blood pressure determinations in the recumbent position should be made to check for hypertension. In the infant, supplementation of 3–5 mEq Na⁺/kg/d by adding a solution of 4 mg/mL to formula or breast milk is generally required until table foods are introduced.

C. Corticosteroids in Patients with Adrenocortical Insufficiency Who Undergo Surgery

1. Before operation—Hydrocortisone sodium succinate, 30–50 mg/m² IM or intravenously 1 hour before surgery.
2. During operation—Hydrocortisone sodium succinate, 25–100 mg intravenously with 5%–10% glucose in saline as a continuous drip throughout surgery.

3. During recovery—Hydrocortisone sodium succinate, 12.5 mg/m² intravenously every 4–6 hours until oral doses are tolerated. The oral hydrocortisone dose of three to five times the maintenance dose is continued until the acute stress is over, at which time the patient can be returned to the maintenance dose.

Course & Prognosis

The course of acute adrenal insufficiency is rapid, and death may occur within a few hours, particularly in infants, unless adequate treatment is given. Spontaneous recovery is unlikely. Patients who have received long-term treatment with adrenocorticosteroids may exhibit adrenal collapse if they undergo surgery or other acute stress. Pharmacologic doses of glucocorticoids during these episodes may be needed throughout life. In all forms of acute adrenal insufficiency, the patient should be observed carefully once the crisis has passed and evaluated with laboratory tests to assess the degree of permanent adrenal insufficiency.

Patients with chronic adrenocortical insufficiency who receive adequate therapy can lead normal lives.

Elevation of plasma 17-hydroxyprogesterone concentrations in the most common form; may be associated with hyponatremia, hyperkalemia, and metabolic acidosis, particularly in newborns.

General Considerations

Autosomal recessive mutations in the enzymes of adrenal steroidogenesis in the fetus cause impaired cortisol biosynthesis with increased ACTH secretion. ACTH excess subsequently results in adrenal hyperplasia with increased production of adrenal hormone precursors which are conveyed through the unblocked androgen pathway with resulting increase in androgen production. Increased pigmentation, especially of the scrotum, labia majora, and nipples, is common with excessive ACTH secretion. CAH is most commonly (> 90% of patients) the result of homozygous or compound heterozygous mutations in the cytochrome P-450 C21 (CYP21A2) gene causing 21-hydroxylase deficiency (see Figure 34–8). In its severe form, excess adrenal androgen production starting in the first trimester of fetal development causes virilization of the female fetus and life-threatening hypovolemic, hyponatremic shock (adrenal crisis) in the newborn. There are also other enzyme defects that less commonly result in CAH. The clinical syndromes associated with these defects are shown in Figure 34–8 and Table 34–10.

Studies of patients with 21-hydroxylase deficiency indicate that the clinical type (salt-wasting or non–salt-wasting) is usually consistent within a kindred and that a close genetic linkage exists between the 21-hydroxylase gene and the human leukocyte antigen complex on chromosome 6. Prenatal diagnosis is now possible by allele-specific PCR or direct sequencing of the fetal CYP21A2 gene. This can be done when there is a known index case in the family. Population studies indicate that the defective gene is present in 1:250–1:100 people and that the worldwide incidence of the disorder is 1:15,000 with increased incidence is certain ethnic groups. Mass screening for this enzyme defect, using a microfilter paper technique to measure serum 17-hydroxyprogesterone, has been established in all 50 U.S. states and many other countries worldwide.

Nonclassic presentations of 21-hydroxylase deficiency have been reported with increasing frequency. Affected persons have a normal phenotype at birth but may develop evidence of virilization during later childhood, adolescence, or early adulthood. In these cases, results of hormonal studies are characteristic of 21-hydroxylase deficiency with cosyntrpin stimulated 17-OHP levels being intermediate between those of nonaffected individuals and those with the classic form of the disease. Many individuals with the nonclassic form of the disease can be asymptomatic or only mildly symptomatic and do not need treatment. However, they can carry a severe CYP21A2 mutation and produce offspring with the classic form. Thus, it is recommended that these individuals should receive genetic counseling.
**Clinical Findings**

**A. Symptoms and Signs**

1. **In females**—Abnormality of the external genitalia varies from mild enlargement of the clitoris to complete fusion of the labioscrotal folds, forming an empty malrotated scrotum, a penile urethra, a penile shaft, and with clitoral enlargement sufficient to form a normal-sized glans (see Figure 34–7). Signs of adrenal insufficiency (salt loss) may occur in the first days of life but more typically appear in the second or third week. Rarely, signs of adrenal insufficiency do not occur for months or years. With milder enzyme defects, salt loss may not occur, and virilization predominates (simple virilizing form). In untreated non–salt-losing 21-hydroxylase deficiency congenital adrenal hyperplasia (CAH) may have normal aldosterone production and serum electrolytes, but some children have normal aldosterone production and serum electrolytes at the expense of elevated plasma renin activity and are, by definition, compensated salt-wasters. These children usually receive mineralocorticoid as well as glucocorticoid treatment. Children with 21-hydroxylase deficiency CAH should therefore have documented normal plasma renin activity in addition to normal serum electrolytes before they are considered non–salt-wasters.

2. **In males**—The male infant usually appears normal at birth but may present with salt-losing crisis in the first 2–4 weeks of life. In milder forms, salt-losing crises may not occur. In this circumstance, enlargement of the penis and increased pigmentation may be noted during the first few months. Other symptoms and signs are similar to those of affected females. The testes are not enlarged except in the rare male in whom aberrant adrenal cells (adrenal rests) are present in the testes, producing unilateral or asymmetrical bilateral enlargement. In the rare isolated defect of STAR protein, 17α-hydroxylase, or 3β-hydroxysteroid dehydrogenase activity, ambiguous genitalia may be present because of impaired androgen production (see Figure 34–8). Individuals with PORD present with skeletal malformations similar to the Antler Bixley syndrome in addition to genital ambiguity. Rare cases of 17α-hydroxylase mutations affecting only the 17–20 lyase functions of the enzyme have been reported. In those cases, patients present with isolated androgen deficiency and normal cortisol and aldosterone levels.

**B. Laboratory Findings**

1. **Blood**—Hormonal studies are essential for accurate diagnosis. Findings characteristic of the enzyme deficiencies are shown in Table 34–10.

2. **Genetic studies**—Rapid chromosomal diagnosis should be obtained in any newborn with ambiguous genitalia.

DHEA, dehydroepiandrosterone; 17-OHP, 17-hydroxyprogesterone.

*Children with “simple virilizing (non–salt-wasting)” forms of 21-hydroxylase deficiency congenital adrenal hyperplasia (CAH) may have normal aldosterone production and serum electrolytes, but some children have normal aldosterone production and serum electrolytes at the expense of elevated plasma renin activity and are, by definition, compensated salt-wasters. These children usually receive mineralocorticoid as well as glucocorticoid treatment. Children with 21-hydroxylase deficiency CAH should therefore have documented normal plasma renin activity in addition to normal serum electrolytes before they are considered non–salt-wasters.
3. Urine—The diagnosis of P450 oxidoreductase deficiency is best done by gas chromatography/mass spectrometry analysis of urinary steroid metabolites, as serum steroids can be misleading. Pathognomonic findings include: increased pregnenolone and progesterone metabolites, increased 17-OHHP metabolites, and decreased androgen metabolites.

C. Imaging

Ultrasonography, CT scanning, and MRI may be useful in defining pelvic anatomy or enlarged adrenals or in localizing an adrenal tumor. Contrast-enhanced radiographs of the vagina and pelvic ultrasonography may be helpful in delineating the internal anatomy in a newborn with ambiguous genitalia.

▶ Treatment

A. Medical Treatment

Treatment goals in CAH are to replace deficient steroids with the smallest dose of glucocorticoid that will produce normalization of growth velocity and skeletal maturation by adequately suppressing excess build-up of androgen precursors. Excessive glucocorticoids cause the undesirable side effects of Cushing syndrome. Mineralocorticoid replacement sustains normal electrolyte homeostasis, but excessive mineralocorticoids cause hypertension and hypokalemia. Undervirilized males with the less frequent forms of CAH may require adult androgen replacement therapy in addition to glucocorticoid and mineralocorticoid replacement.

1. Glucocorticoids—Supraphysiologic doses of hydrocortisone are often needed to suppress androgen excess in CAH. Initially, parenteral or oral hydrocortisone (30–50 mg/m²/d) suppresses abnormal adrenal steroidogenesis within 2 weeks. When adrenal suppression has been accomplished, as evidenced by normalization of serum 17-hydroxyprogesterone, patients are placed on maintenance doses of 10–15 mg/m²/d in three divided doses. Dosage is adjusted to maintain normal growth rate and skeletal maturation. Various serum and urine androgens have been used to monitor therapy, including 17-hydroxyprogesterone, androstenedione, and urinary pregnanetriol. No one test is universally accepted. In adolescent girls, normal menses are a sensitive index of the adequacy of therapy. Therapy should be continued throughout life in both males and females because of the possibility of malignant degeneration of the hyperplastic adrenal gland. In pregnant females with CAH, suppression of adrenal androgen secretion is critical to avoid virilization of the fetus, particularly a female fetus. Suppression of adrenal androgen production is best begun before conception. Hydrocortisone is the preferred choice for glucocorticoid replacement therapy in pregnant women with CAH because it does not cross the placenta.

2. Mineralocorticoids—Fludrocortisone, 0.05–0.15 mg, is given orally once a day or in two divided doses. Periodic monitoring of blood pressure and plasma renin activity are recommended to adjust dosing.

B. Surgical Treatment

For affected females, consultation with a urologist or gynecologist experienced in female genital reconstruction should be arranged as soon as possible during infancy.

▶ Course & Prognosis

When therapy is initiated in early infancy, abnormal metabolic effects and progression of masculinization can be avoided. Treatment with glucocorticoids permits normal growth, development, and sexual maturation. If not adequately controlled, CAH results in sexual precocity and masculinization throughout childhood. Affected individuals will be tall as children but short as adults because of a rapid rate of skeletal maturation and premature closure of the epiphyses. If treatment is delayed or inadequate until somatic development is completed (12–14 years as determined by bone age), true central precocious puberty may occur in males and females.

Patient education stressing lifelong therapy is important to ensure compliance in adolescence and later life. Virilization and multiple surgical genital reconstructions are associated with a high risk of psychosexual disturbances in female patients. Ongoing psychological evaluation and support is a critical component of care.

ADRENOCORTICAL HYPERFUNCTION (CUSHING DISEASE, CUSHING SYNDROME)

▶ Cushing Syndrome.
▶ Truncal adiposity, thin extremities, moon facies, muscle wasting, weakness, plethora, easy bruising, purple...
Hypertension, osteoporosis, and glycosuria.

- Elevated serum corticosteroids, low serum potassium, eosinopenia, and lymphopenia.

**General Considerations**

Cushing syndrome may result from excessive secretion of adrenal steroids autonomously (adenoma or carcinoma), excess pituitary ACTH secretion (Cushing disease), ectopic ACTH secretion, or chronic exposure to exogenous glucocorticoids. In children younger than 12 years, Cushing syndrome is usually iatrogenic (secondary to exogenous ACTH or glucocorticoids). It may rarely be due to adrenal tumor, adrenal hyperplasia, pituitary adenoma, or extrapituitary ACTH-producing tumor.

**Clinical Findings**

A. Symptoms and Signs

1. Excess glucocorticoid—Manifestations include adiposity, most marked on the face, neck, and trunk (a fat pad in the interscapular area is characteristic); fatigue; plethoric facies; purplish striae; easy bruising; osteoporosis; hypertension; glucose intolerance; back pain; muscle wasting and weakness; and marked retardation of growth and skeletal maturation.

2. Excess mineralocorticoid—Patients have hypokalemia, mild hypernatremia with water retention, increased blood volume, edema, and hypertension.

3. Excess androgen—Hirsutism, acne, and varying degrees of virilization are present. Menstrual irregularities occur in older girls.

B. Laboratory Findings

1. Blood

   - **Plasma cortisol**—Values are elevated, with loss of normal diurnal variation. Determination of cortisol level between midnight and 2 AM may be a sensitive indicator of the loss of diurnal variation.

   - **Serum chloride and potassium**—Both values are usually low, but serum sodium and bicarbonate concentrations may be elevated with metabolic alkalosis.

   - **Serum ACTH**—ACTH concentration is decreased in adrenal tumor and increased with ACTH-producing pituitary or extrapituitary tumors.

   - **CBC**—Polymorphonuclear leukocytosis with lymphopenia and eosinopenia are common. Polycythemia occurs.

2. **Salivary cortisol**—This is a less invasive means by which to measure serial cortisol values, and the tests may be performed at home. Salivary cortisol obtained at midnight is a highly specific and sensitive test for hypercortisolism.

3. **24-Hour urinary free cortisol excretion**—This value is elevated. It is considered the most useful initial test to document hypercortisolism, although midnight salivary cortisol is considered a reasonable and more practical alternative. The urinary free cortisol/creatinine ratio is usually measured to correct for incomplete 24 hour collections.

4. **Response to dexamethasone suppression testing**—Suppression of adrenal function by a small dose (0.5–1.0 mg) of dexamethasone is seen in obese children who may have elevated urinary free cortisol excretion, but not in children with an ACTH-secreting tumor or adrenal tumor. Larger doses (4–16 mg/d in four divided doses) of dexamethasone cause suppression of adrenal activity when the disease is due to ACTH hypersecretion by a pituitary tumor, whereas hypercortisolism due to adrenal adenomas or adrenal carcinomas is rarely suppressed.

5. **CRH test**—The CRH stimulation test, in conjunction with petrosal sinus sampling, is effective in distinguishing pituitary and ectopic sources of ACTH excess and for lateralization of pituitary sources prior to surgery.

C. Imaging

Pituitary imaging may demonstrate a pituitary adenoma. Adrenal imaging by CT scan may demonstrate adenoma or bilateral hyperplasia. Radionuclide studies of the adrenals may be useful in complex cases. Osteoporosis, evident first in the spine and pelvis, with compression fractures may occur in advanced cases. Skeletal maturation is usually delayed.

**Differential Diagnosis**

Children with exogenous obesity accompanied by striae and hypertension are often suspected of having Cushing syndrome. The child’s height, growth rate, and skeletal maturation are helpful in differentiating the two. Children with Cushing syndrome have a poor growth rate, relatively short stature, and delayed skeletal maturation, while those with exogenous obesity usually have a normal or slightly increased growth rate, normal to tall stature, and advanced skeletal maturation. The color of the striae (purplish in Cushing syndrome, pink in obesity) and the distribution of the obesity may assist in differentiation. The urinary-free cortisol excretion (in milligrams per gram of creatinine) may be mildly elevated in obesity, but midnight salivary cortisol is normal, and cortisol secretion is suppressed by a relatively small dose of dexamethasone (see “Response to dexamethasone suppression testing”).
Treatment

In all cases of primary adrenal hyperfunction due to tumor, surgical removal is indicated if possible. Glucocorticoids should be administered parenterally in pharmacologic doses during and after surgery until the patient is stable. Supplemental oral glucocorticoids, potassium, salt, and mineralocorticoids may be necessary until the suppressed contralateral adrenal gland recovers, sometimes over a period of several months. The use of mitotane, a DDT derivative that is toxic to the adrenal cortex, and aminoglutethimide, an inhibitor of steroid synthesis, have been suggested, but their efficacy in children with adrenal tumors has not been determined. Pituitary microadenomas may respond to pituitary surgery or irradiation.

Prognosis

If the tumor is malignant, the prognosis is poor if it cannot be completely removed. If it is benign, cure is to be expected following proper preparation and surgery.

Primary Hyperaldosteronism

Primary hyperaldosteronism may be caused by an adrenal adenoma or adrenal hyperplasia. It is characterized by paresthesias, tetany, weakness, nocturnal enuresis, periodic paralysis, low serum potassium and elevated serum sodium levels, hypertension, metabolic alkalosis, and production of large volume, alkaline urine with low specific gravity. The specific gravity does not respond to vasopressin. Glucose tolerance test is frequently abnormal. Plasma and urinary aldosterone are elevated. In contrast to renal disease or Bartter syndrome, plasma renin activity is suppressed, creating a high aldosterone-renin ratio. In patients with adrenal tumor, ACTH may further increase the excretion of aldosterone. Marked improvement after the administration of an aldosterone antagonist such as spironolactone may be of diagnostic value.

Primary hyperaldosteronism is rare in pediatrics. However, there are three recognized genetic causes (types I–III). Type I occurs due to inheritance of a hybrid of the genes encoding 11β-hydroxylase and aldosterone synthase. Type III was recently described and results from mutations in the KCNJ5 gene encoding a K+ channel. Somatic mutations of this gene are also seen in later onset hyperaldosteronism. The genetic cause for type II is unknown.

Treatment is with glucocorticoids (glucocorticoid remediable hyperaldosteronism or familial hyperaldosteronism type I), spironolactone (familial hyperaldosteronism type II), or subtotal or total adrenalectomy for hyperplasia, and surgical removal if a tumor is present.

Uses of Glucocorticoids & Adrenocorticotropic Hormone in Treatment of Nonendocrine Diseases

Glucocorticoids are used for their anti-inflammatory and immunosuppressive properties in a variety of conditions in childhood. Pharmacologic doses are necessary to achieve these effects, and side effects are common. Numerous synthetic preparations possessing variable ratios of glucocorticoid to mineralocorticoid activity are available (Table 34–11).

Actions

Glucocorticoids exert a direct or permissive effect on virtually every tissue of the body; major known effects include the following:

1. Gluconeogenesis in the liver
2. Stimulation of fat breakdown (lipolysis) and redistribution of body fat
3. Catabolism of protein with an increase in nitrogen and phosphorus excretion
4. Decrease in lymphoid and thymic tissue and a decreased cellular response to inflammation and hypersensitivity
5. Alteration of CNS excitation
6. Retardation of connective tissue mitosis and migration; decreased wound healing
7. Improved capillary tone and increased vascular compartment volume and pressure

Side Effects of Therapy

When prolonged use of pharmacologic doses of glucocorticoids is necessary, clinical manifestations of Cushing syndrome are common. Side effects may occur with the use
of synthetic exogenous agents by any route, including inhalation and topical administration, or with the use of ACTH. Use of a larger dose of glucocorticoids given once every 48 hours (alternate-day therapy) lessens the incidence and severity of some of the side effects (Table 34–12).

### Tapering of Pharmacologic Doses of Steroids

Prolonged use of pharmacologic doses of glucocorticoids causes suppression of ACTH secretion and consequent

adrenal atrophy. The abrupt discontinuation of glucocorticoids may result in adrenal insufficiency. ACTH secretion generally does not restart until the administered steroid has been given in subphysiologic doses (< 6 mg/m²/d orally) for several weeks.

If pharmacologic glucocorticoid therapy has been given for less than 10–14 days, the drug can be discontinued abruptly (if the condition for which it was prescribed allows) because adrenal suppression will be short-lived. However, it is advisable to educate the patient and family about the signs and symptoms of adrenal insufficiency in case problems arise.

If tapering is necessary in treating the condition for which the glucocorticoid is prescribed, a reduction of 25%–50% every 2–7 days is sufficiently rapid to permit observation of clinical symptomatology. An alternate-day schedule (single dose given every 48 hours) will allow for a 50% decrease in the total 2-day dosage while providing the desired pharmacologic effect. If tapering is not required for the underlying disease, the dosage can be rapidly decreased safely to the physiologic range. Although a rapid decrease in dose to the physiologic range will not lead to frank adrenal insufficiency (because adequate exogenous cortisol is being provided), some patients may experience a steroid withdrawal syndrome, characterized by malaise, insomnia, fatigue, and loss of appetite. These symptoms may necessitate a two- or three-step decrease in dose to the physiologic range.

Once a physiologic equivalent dose (8–10 mg/m²/d hydrocortisone or equivalent) is achieved and the patient’s underlying disease is stable, the dose can be decreased to 4–5 mg/m²/d given only in the morning. This will allow the adrenal axis to recover. After this dose has been given for 4–6 weeks, assessment of endogenous adrenal activity is estimated by obtaining fasting plasma cortisol concentrations between 7 and 8 AM prior to the morning steroid dose. When an alternate-day schedule is followed, plasma cortisol is measured the morning before treatment. Plasma cortisol concentration in the physiologic range (> 10 mg/dL) indicates return of basal physiologic adrenal rhythm. Exogenous steroids may then be discontinued safely, although it is advisable to continue giving stress doses of glucocorticoids when appropriate until recovery of the response to stress has been documented.

After basal physiologic adrenal function returns, the adrenal reserve or capacity to respond to stress and infection can be estimated by the low-dose ACTH stimulation test, in which 1 mcg of synthetic ACTH (cosyntropin) is administered intravenously. Plasma cortisol is measured prior to (zero time) and at 45–60 minutes after the infusion. A plasma cortisol concentration greater than 18 mg/dL at 60 minutes indicates a satisfactory adrenal reserve.

Even if the results of testing are normal, patients who have received prolonged treatment with glucocorticoids may develop signs and symptoms of adrenal insufficiency during acute stress, infection, or surgery for months to years after treatment has been stopped. Careful monitoring, and the use of stress doses of glucocorticoids, should be considered during severe illnesses and surgery.

Pheochromocytoma is an uncommon tumor, but up to 10% of reported cases occur in pediatric patients. The tumor can be located wherever chromaffin tissue (adrenal medulla, sympathetic ganglia, or carotid body) is present, possibly from decreased apoptosis of neural crest cells during development. It may be multiple, recurrent, and sometimes malignant. Familial forms include pheochromocytomas associated with the dominantly inherited neurofibromatosis type 1, MEN type 2, and von Hippel-Lindau syndromes, as well as mutations of the succinate dehydrogenase genes. Neuroblastomas, ganglioneuromas, and other neural crest tumors, as well as carcinoid tumors, may secrete pressor amines and mimic pheochromocytoma.

The symptoms of pheochromocytoma are generally caused by excessive secretion of epinephrine or norepinephrine and most commonly include headache, sweating, tachycardia, and hypertension. Other symptoms are anxiety, dizziness, weakness, nausea and vomiting, diarrhea, dilated pupils, blurred vision, abdominal and precordial pain, and vasomotor instability (flushing and postural hypotension). Sustained symptoms may lead to cardiac, renal, optic, or cerebral damage.

Laboratory diagnosis is possible in more than 90% of cases. Serum and urine catecholamines are elevated, but abnormalities may be limited to periods of symptomatology or paroxysm. Plasma-free metanephrine level (phenoxybenzamine, tricyclic antidepressants, and β-adrenoceptor blockers can create false-positive results) is the most sensitive test and the gold standard for diagnosis. Levels three times the normal range are diagnostic. Intermediate values may
require additional testing, with urinary vanillylmandelic acid and urinary total metanephrines providing the highest specificity. Provocative tests using histamine, tyramine, or glucagon and the phenolamine tests may be abnormal but are dangerous and are rarely necessary. After demonstrating a tumor biochemically, imaging methods including CT or MRI are used to localize the tumor. When available, functional ligands such as (123)I-MIBG, [18F]DA positron emission tomography scanning, and somatostatin receptor scintigraphy (with either [125I]Tyr3-octreotide or [111In] DTPA-octreotide) are useful in further diagnostic evaluation.

Laparoscopic tumor removal is the treatment of choice; however, the procedure must be undertaken with great caution and with the patient properly stabilized. Oral phenoxybenzamine or intravenous phentolamine is used preoperatively. Profound hypotension may occur as the tumor is removed but may be controlled with an infusion of noradrenaline, which may have to be continued for 1–2 days. Unless irreversible secondary vascular changes have occurred, complete relief of symptoms is to be expected after recovery from removal of a benign tumor. However, prognosis is poor in patients with metastases, which occur more commonly with large, extra-adrenal pheochromocytomas.

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Polyuria, polydipsia, and weight loss.
- Hyperglycemia and glucosuria often with ketonemia/ketonuria.

GENERAL CONSIDERATIONS

**Type 1 diabetes** (T1D) is the most common type of diabetes mellitus in people younger than 20 years, but can develop at any age and most cases are diagnosed after age 20. The classical presentation includes increased thirst (polydipsia), urination (polyuria), and weight loss; however, the patient may be overweight or even obese. T1D is further divided into T1a (autoimmune) (~95% of the cases) and T1b (idiopathic) diabetes. T1a diabetes is marked by presence of autoantibodies to islet cell autoantigens (insulin, GAD65, IA-2, and ZnT8) and high-risk HLA (human leucocyte antigen) haplotypes (DR4, DQ8, and DR3/DQ2). Insulin production, measured by fasting or stimulated C-peptide levels, is usually low. In the United States, T1D affects an estimated 1.5 million people, including 160,000–200,000 patients younger than age 20 (~25,000 diagnosed annually).

**Type 2 diabetes** (T2D) is a heterogeneous phenotype diagnosed most often in persons older than age 40 who are usually obese and initially not insulin-dependent. T2D is rare before age 10, but has increased in frequency in older children as a consequence of the epidemic of obesity. The vast majority of the 26 million patients with diabetes in the United States have T2D, but only approximately 16,000 patients are younger than age 20 (~5000 diagnosed annually).

**Monogenic forms of diabetes** can be diagnosed at any age. They account for less than 1% of childhood diabetes, but form the majority of cases diagnosed before the ninth month of life. Neonatal diabetes is transient in about half of the cases; if persistent, it presents a significant clinical challenge. Some infants respond better to sulfonylurea than insulin. Maturity-onset diabetes of the young (MODY) presents as a nonketotic and usually non–insulin-dependent diabetes in the absence of obesity or islet autoantibodies. A strong family history of early-onset diabetes is common. The most frequent forms are due to mutations in glucokinase or hepatic nuclear factor 1 or 2 genes. Glucokinase mutations rarely require therapy; other forms respond to oral hypoglycemic agents or insulin. Commercial and research-oriented genotyping services are available to aid correct diagnosis.

Pathogenesis

**A. Type 1 Diabetes**

Type 1 diabetes results from autoimmune destruction of the insulin-producing β cells of the pancreatic islets. This destruction occurs over months or years and symptoms do not appear until most of the pancreatic islets have been destroyed.

The incidence is the highest in children of European ancestry, followed by African Americans and Hispanics; the rates are low in Asians and Native Americans.

About 6% of siblings or offspring of persons with T1D also develop diabetes (compared with prevalence in the general population of 0.2%–0.3%). However, fewer than 10% of children newly diagnosed with T1D have a parent or sibling with the disease. More than 90% of children with T1D carry at least one of the two high-risk HLA haplotypes—DR4/DQ8 or DR3/DQ2—and 40% of US children diagnosed before age of 10 years have both (one from each parent), compared with only 2.5% of the general population. Over 30 non-HLA genetic variants have also been implicated.

Since the 1950s, the incidence of T1D has increased dramatically worldwide, doubling approximately every
20 years. Despite much research of early childhood infections and diet, the environmental factor(s) responsible for this epidemic are poorly defined. There is no effective prevention as of 2013; however, screening of high-risk groups for islet autoantibodies and intensive follow-up reduces the severity of the presentation.

B. Type 2 Diabetes

Type 2 diabetes has a strong genetic component, although the inherited defects vary in different families. Obesity, particularly central, and lack of exercise are major causes, but rarely sufficient alone to cause diabetes in youth. Most pediatric patients come from low socioeconomic strata and dysfunctional families; some present with psychiatric disorders. Obesity, T2D, and associated insulin resistance adversely affect cardiovascular health. Acanthosis nigricans, a thickening and darkening of the skin over the posterior neck, armpits, or elbows, is present in many obese children and has occasionally contributed to the diagnosis of T2D.

Prevention

A. Type 1 Diabetes

Islet autoantibodies are present for months to years prior to diagnosis in the serum of patients who develop T1a diabetes. Free antibody screening is now available for families having a relative with type 1 diabetes (1-800-425-8361). These antibodies, which do not mediate β-cell destruction, offer a useful screening tool. The β-cell damage is mediated by T lymphocytes. Immunosuppression at different checkpoints of the autoimmune process can slow down the damage, but has no durable effect when stopped. Immunomodulation, including induction of tolerance to islet autoantigens, with or without immunosuppression, is an area of intensive research.

B. Type 2 Diabetes

The Diabetes Prevention Program in adults with impaired glucose tolerance found that 30 minutes of exercise per day (5 d/wk) and a low-fat diet reduced the risk of diabetes by 58%. Taking metformin also reduced the risk of T2D by 31%.

Clinical Findings

A combination of polyuria, polydipsia, and weight loss in a child is unique to diabetes. Unfortunately, these symptoms are often missed by primary care providers or even emergency department staff. The frequency of diabetic ketoacidosis (DKA) in US children has not decreased in the past 20 years and is approaching 40%, a sign of poor provider and poor community awareness. More than half of DKA patients were observed by a provider in days preceding diagnosis and obvious symptoms and signs were missed. In contrast, only 10%–20% of newly diagnosed children in Scandinavia or Canada present with DKA. This embarrassing statistic could be greatly improved with better history taking and point-of-care urine analysis. Initial diagnosis can be easily confirmed by blood glucose and ketones measurement using widely available and inexpensive meters.

The clinical presentation of DKA includes abdominal pain, nausea, and vomiting that can mimic an acute abdomen. The patients are mildly to moderately dehydrated (5%–10%), may have Kussmaul respiration, and become progressively somnolent and obtunded. The distribution of diagnosis has shifted to younger age; infants, toddlers, and preschool age children are at particular risk. They often have symptoms of minor infection or gastrointestinal upset. A heavy diaper in a dehydrated child without diarrhea should always flash an alarm. Blood or urine glucose levels could be lifesaving. Blood glucose higher than 200 mg/dL in a child is always abnormal and must be promptly and meticulously followed in consultation with a pediatric endocrinology service. If the presentation is mild and an outpatient diabetes education service is available, hospitalization is usually not necessary.

Transient, “stress-” or steroid-induced hyperglycemia can occur with illness. In a well child, the diagnosis must not be based on a single plasma glucose test or a borderline result obtained using a glucose meter. Our center routinely tests such children for islet autoantibodies to rule out ongoing islet autoimmunity. Absence of the three most available autoantibodies (to insulin, GAD, and IA-2) provides 80% negative predictive value. If HbA1c is normal, we recommend home monitoring of blood glucose for several days. In children progressing to overt diabetes, hyperglycemia after dinner is usually the initial abnormality, which is detectable by self-blood glucose monitoring at home.

In the presence of typical symptoms, a random blood glucose level above 200 mg/dL (11 mmol/L) (confirmed on a CLIA [Clinical Laboratory Improvement Amendments]-certified instrument) is sufficient to make the diagnosis of diabetes. An oral glucose tolerance test is rarely necessary in children. In borderline or asymptomatic cases, a fasting plasma glucose level over 126 mg/dL (7 mmol/L) or a plasma glucose level above 200 mg/dL (11.1 mmol/L) 2 hours after an oral glucose load (1.75 g glucose/kg up to a maximum of 75 g) on 2 separate days confirms the diagnosis. Impaired (not yet diabetic) fasting glucose values are 100–125 mg/dL (5.5–6.9 mmol/L) and impaired 2-hour values are 140–200 mg/dL (7.8–11.1 mmol/L). Children with impaired fasting glucose or impaired glucose tolerance are at high risk of T2D and require careful follow-up and lifestyle modification with weight loss, if obese.

Treatment

Major variables in T1D treatment are insulin therapy, diet, exercise, and psychosocial support. All must be addressed to achieve safe and effective metabolic control. At present, the
 safest recommendation for glycemic control in children is to achieve an HbA1c < 7.5% or the lowest that can be sustained without severe hypoglycemia or frequent moderate hypoglycemia. The HbA1c level reflects the average blood glucose levels over the previous 3 months. Each child should have targets individually determined.

Intensive diabetes management includes: (1) three or more insulin injections per day, or insulin pump therapy based on carbohydrate counting; (2) at least four blood glucose determinations per day; (3) ketone monitoring during hyperglycemia; and (4) frequent contact with a diabetes healthcare provider. The Diabetes Control and Complications Trial (DCCT) showed that this approach improved HbA1c to approximately 7% and significantly reduced the risk for retinal, renal, cardiovascular, and neurologic complications of diabetes.

A. Patient and Family Education

Education about diabetes for all family members is essential for the home management of diabetes. The use of an educational book (see Understanding Diabetes and Understanding Insulin Pumps and Continuous Glucose Monitors) can be very helpful to the family. All caregivers need to learn about diabetes, how to give insulin injections, perform home blood glucose monitoring, and handle acute complications. Although teenagers can be taught to perform many of the tasks of diabetes management, they do better when supportive, not overbearing, parents continue to be involved in management of their disease. Children younger than age 12 years cannot reliably administer insulin without adult supervision because they may lack fine motor control and/or may not understand the importance of accurate dosage.

B. Insulin

Insulin has three key functions: (1) it allows glucose to pass into the cell for oxidative utilization; (2) it decreases the physiologic production of glucose, particularly in the liver; and (3) it turns off lipolysis and ketone production.

1. Treatment of new-onset diabetes—Children presenting in DKA (pH < 7.30 or bicarbonate < 15 mEq/L in presence of hyperglycemia and ketosis/ketonemia) require intravenous insulin in addition to replacement of fluids and electrolytes. Regular insulin is given as a continuous drip at a rate of 0.05–0.1 U/kg/h to achieve drop in blood glucose of approximately 100 mg/dL per hour. Giving an IV insulin bolus of insulin before the completion of the initial fluid bolus has been associated with brain edema. Fast-acting insulin analogs have no advantage over regular insulin when given intravenously.

In children who present without DKA and have adequate oral intake, the initial insulin dose can be administered subcutaneously as 0.2 U/kg of short-acting insulin (regular) or, preferentially, rapid-acting analog: lispro (Humalog), aspart (NovoLog), or glulisine (Apidra). At the same time, 0.2–0.3 U/kg of long-acting insulin analog—glargine (Lantus) or detemir (Levemir)—can be administered subcutaneously to limit the need for multiple insulin injections. This usually suffices for the initial 12–24 hours preceding systematic diabetes education.

The dose is adjusted with each injection during the first week. The rule of thumb is to start insulin at the low end of the estimated daily requirement and titrate it up based on frequent (q2–4h) blood-glucose monitoring. The initial daily dose of insulin is higher in the presence of ketosis, infection, obesity, or steroid treatment. It also varies with age and severity of onset. A total subcutaneous daily dose of 0.3–0.7 U/kg/day may suffice in prepubertal children, while pubertal or overweight children and those with initial HbA1c > 12% commonly require 1.0–1.5 U/kg/day of insulin during the initial week of treatment.

The insulin dose peaks about 1 week after diagnosis and decreases slightly with the waning of glucotoxicity and voracious appetite. Approximately 3–6 weeks after diagnosis, most school-children and adolescents experience a partial remission or “honeymoon period.” Temporary decrease in the insulin dose during this period is necessary to avoid severe hypoglycemia. The remission tends to last longer in older children, but is rarely complete and never permanent. Other types of diabetes should be considered in patients with unusually low insulin requirements.

2. Long-term insulin dosage—Children usually receive a rapid-acting insulin to cover food intake or correct high blood glucose and a long-acting insulin to suppress endogenous hepatic glucose production. This is achieved by combining insulins with the desired properties. Understanding the onset, peak, and duration of insulin activity is essential (Table 35–1).

Nearly all children diagnosed with T1D at our center receive a basal-bolus multiple daily injection (MDI) treatment. This usually consists of 3–4 injections (boluses) of rapid-acting analog before meals and 1–2 injections of long-acting analog insulin. The dose of premeal rapid-acting insulin is calculated based on anticipated carbohydrate content of the meal and additional insulin to correct for high blood glucose, if needed. Sliding scales for dosing of rapid-acting insulin are helpful initially, while families learn carbohydrate counting. This shortcut assumes that the content of carbohydrates does not vary, for example in dinner, from day to day, this may lead to significant under- and overdosing.

Children younger than 4 years usually need 1 or 2 units of rapid-acting insulin to cover carbohydrate intake. Children aged 4–10 years may require up to 4 units of rapid-acting insulin to cover breakfast and dinner, whereas 4–10 units of rapid-acting insulin are used in older children. These estimates do not include correction for high blood glucose.
Families gradually learn to make small weekly adjustments in insulin dosage based on home blood glucose testing. Rapid-acting analog insulin is given 10–20 minutes before eating to account for delay in insulin action. If slower human regular insulin is used, the injections should be given 30–60 minutes before meals—rarely a practical option. In young children who eat unpredictably, it is often necessary to wait until after the meal to decide on the appropriate dose of rapid-acting insulin, which is a compromise between avoiding hypoglycemia and tolerating hyperglycemia after meals.

A long-acting analog insulin glargine (Lantus) or detemir (Levemir) is given once or twice a day to maintain basal insulin levels between meals. Daily adjustments in long-acting insulin dose usually are not needed. However, decreases should be made for heavy activity (eg, sports, hikes, or over-night events).

In the past, most children would receive 2 injections per day of a rapid-acting insulin and an intermediate-acting insulin (NPH), often mixed just before injection. About two-thirds of the total dosage would be given before breakfast and the remainder before dinner. This regimen has been shown to be inferior in achieving recommended HbA1c levels and avoiding hypoglycemia, compared with the basal-bolus regimen described above. Analog insulin (glargine, detemir) works more efficiently than NPH. When changing a patient from NPH insulin to an analog, initially only 50% of the daily units of long-acting insulin is recommended.

### 3. Insulin pump treatment

Continuous subcutaneous insulin (insulin pump) therapy is the best way to restore the body’s physiologic insulin profile. The pump delivers a variable programmed basal rate that corresponds to the diurnal variation in insulin needs. Prepubertal children require higher basal rate in the early part of night, while postpubertal patients who experience the “dawn phenomenon” require higher rates in the morning. The user initiates bolus doses before meals and to correct hyperglycemia. Most pumps can receive wireless transmission of test results from glucose meters, but the patient or caregiver must still manually enter the amount of carbohydrate being consumed. The pump calculates the amount of insulin needed for a meal or correction based on previously entered parameters which include: insulin-to-carbohydrate ratios, insulin sensitivity factor, glycemic target, and duration of insulin action (set at 3–4 hours to protect from accumulating too much insulin). The user may override the suggestion or press a button to initiate the bolus.

Most clinical trials have demonstrated better HbA1c and less severe hypoglycemia with pump therapy, compared to MDI. Pump therapy can improve the quality of life in children who have trouble with or fear of injections or who desire greater flexibility in their lifestyle; for example, with sleeping in, sports, or irregular eating. Insulin pumps can be particularly helpful in young children or infants who have multiple meals and snacks and require multiple small doses of rapid-acting insulin. The newer generation of insulin pumps can deliver as little as 0.025 U/h, but higher rates using diluted insulin may be needed for uninterrupted flow.

Compliance problems include infrequent blood glucose testing, not reacting to elevated blood glucose, incorrect carbohydrate counting, or missing the boluses altogether. Side effects of insulin pump treatment include failures of insulin delivery because of a displaced or obstructed infusion set. Insulin pump treatment is significantly more expensive than regimens based on injections. For some patients, pumps may be too difficult to operate, or they cannot comply with the multiple testing and carbohydrate counting requirements, or the pump is unacceptable because of body image issues or extreme physical activity (swimming, contact sports). Disposable pumps are already available and much smaller “patch” pumps are in development.

### 4. “Closed-loop” systems

In the near future, insulin pumps will be directed automatically by a continuous glucose sensor (see section Home Blood Glucose Measurements) with minimal human input. Simple systems are already available that feature, for instance, sensor-initiated automatic suspension of insulin delivery at a predetermined low-glucose level and automatic resumption of the delivery at a safe level. Others, controlling postprandial glycemia are in clinical trials. A number of issues remain to be solved, for example, the accuracy and biocompatibility of
the sensors and infusion sets, limitations (lag time) of the systemic versus intraportal administration of insulin, lack of counterbalancing delivery of glucagon, and optimal delivery algorithms for various meals and activities.

5. Treatment of type 2 diabetes—Treatment of type 2 diabetes in children varies with the severity of the disease. If the HbA1c is still near normal, modification of lifestyle (preferably for the entire family) is the first line of therapy. This must include reducing caloric intake and increasing exercise. With mildly elevated HbA1c (6.2%–8.0%) and no ketosis, metformin is usually started at a dose of 500 mg twice daily along with modification of lifestyle. If needed, and if gastrointestinal adaptation has occurred, the dose can be gradually increased to 1 g twice daily. If the presentation is more severe, with ketosis, the initial treatment is similar to that of T1D, including IV or subcutaneous insulin. Of note, 10% of children with T2D present in DKA. Oral hypoglycemic agents may be tried at a later date, particularly if weight loss has been successful.

C. Diet

A thorough dietary history should be obtained including the family’s dietary habits and traditions, the child’s typical meal times, and patterns of food intake. Nutritional management in children with diabetes does not require a restrictive diet, just a healthy dietary regimen that the children and their families can benefit from. Insulin pump and MDI therapy utilize carbohydrate counting in which the grams of carbohydrate to be eaten are counted and a matching dose of insulin is administered. This plan allows for the most freedom and flexibility in food choices, but it requires expert education and commitment and may not be suitable for many families or situations, such as for school lunches and teenagers. Alternatively to a precise carb counting, “exchanges” are taught to estimate 10- or 15-g servings of carbohydrate.

A constant carbohydrate meal plan was used often in the past with insulin regimens based on NPH and regular insulin, where carbohydrate intake and the amount of insulin were kept relatively constant from day to day. This is now perceived as too restrictive and a potential source of conflict that will lead to poor control.

D. Exercise

Regular aerobic exercise is important for children with diabetes. Exercise fosters a sense of well-being; helps increase insulin sensitivity (a drop in glycemia in response to insulin); and helps maintain proper weight, blood pressure, and HDL-cholesterol levels.

Hypoglycemia during exercise or in the 2–12 hours after exercise can be prevented by careful monitoring of blood glucose before, during, and after exercise; reducing the dosage of the insulin active at the time of (or after) the exercise; and by providing extra snacks. Fifteen grams of glucose usually covers about 30 minutes of exercise. The use of drinks containing 5%–10% dextrose, such as Gatorade, during the period of exercise is often beneficial. Insulin dose for meals as well as the basal insulin pump rate should be reduced before, during, and sometimes after the exercise; the longer and more vigorous the activity, the greater the reduction in insulin dose.

E. Psychological Care

The diagnosis of T1D changes lives of the affected families and brings on relentless challenges. It is impossible to take “vacation” from diabetes without some unpleasant consequences. The stress imposed on the family around the time of initial diagnosis may lead to feelings of shock, denial, sadness, anger, fear, and guilt. Meeting with a counselor to express these feelings at the time of diagnosis helps with long-term adaptation. Children with T1D and their parents often experience difficult adjustment. Persisting adjustment problems may indicate underlying dysfunction of the family or psychopathology of the child or caregiver. Young people with T1D are more frequently diagnosed with and treated for psychiatric disorders, disordered eating, neurocognitive, learning problems, and poor coping skills than the general population.

Routine assessment should be made of developmental adjustment to and understanding of diabetes management, including diabetes-related knowledge, insulin adjustment skills, goal setting, problem-solving abilities, regimen adherence, and self-care autonomy and competence. This is especially important during late childhood and prior to adolescence. General and diabetes-related family functioning such as communication, parental involvement and support, and roles and responsibilities for self-care behaviors need to be assessed. Teaching parents effective behavior management skills, especially at diagnosis and prior to adolescence, emphasizes involvement and support, effective problem-solving, self-management skills, and realistic expectations. Adolescents should be encouraged to assume increased responsibility for diabetes management, but with continued, mutually agreed parental involvement and support. The transition to adult diabetes care should be negotiated and planned between adolescents, their parents, and the diabetes team well in advance of the actual transfer.

F. Home Blood Glucose Measurements

All families must be able to monitor blood glucose levels at least four times daily—and more frequently in patients who have glucose-control problems or intercurrent illnesses. Blood glucose levels can be monitored using any downloadable meter. Target levels when no food has been eaten for 2 or more hours vary according to age (Table 35–2). At least half of the values must be below the upper limit to have a good HbA1c.
The frequency of self-monitoring of blood glucose correlates with improved HbA1c. Patient acceptance may be enhanced by testing on the forearm, in addition to the fingertips; however, that site may be slower to reflect falling blood glucose.

Blood glucose results, insulin dosage, and events, for example, illness, parties, exercise, menses, and episodes of hypoglycemia or ketonuria/ketosis should be recorded in a logbook or downloaded. Regular evaluation by the family helps to see patterns, adjust insulin dosage and, if needed, communicate with healthcare providers. If more than 50% of the values are above the desired range for age or more than 14% below the desired range, the insulin dosage usually needs to be adjusted.

Some families are able to make these changes independently, whereas others need help from the healthcare provider by telephone, fax or email to optimize insulin dose between visits. Children with diabetes should be evaluated by a diabetes provider every 3 months to check compliance, adjust insulin dose according to growth, measure HbA1c, and review blood glucose patterns, as well as for routine review of systems, physical examination, and laboratory tests (Table 35–3).

Home continuous glucose monitoring (CGM) is now routinely available and can tremendously improve diabetes management if used most of the time. Subcutaneous glucose levels are obtained every 1–5 minutes from a sensor placed under the skin. The sensor must be replaced every 7–10 days. The sensor has to be calibrated a couple of times a day using a conventional glucose meter. A transmitter sends glucose levels via radio waves from the sensor to a receiver that can be inside an insulin pump. As with insulin pump therapy, intensive education and follow-up is required, usually at a specialty diabetes center. The user is trained on how to keep the real-time displayed blood glucose “between the lines,” that is, in the personalized range. Low- and high blood glucose alarms can be set and in some systems may change insulin pump delivery rate. At the time of consultation, data from CGM devices and pumps are routinely downloaded for analysis of patterns. CGM systems produced by DexCom and Medtronic are currently available by prescription in the United States.

### G. Prevention of Chronic Complications

#### 1. Maintaining low HbA1c levels

-Elevated HbA1c predicts long-term microvascular and macrovascular complications. HbA1c values approximately 7% compared to values approximately 9% result in greater than 50% reductions in the eye, kidney, cardiovascular, and neurologic complications of diabetes. Normal values vary among laboratories but are usually below 6.2%. In diabetes, the desired ranges are less than 7.5% in children and less than 7% in adults. Higher levels may be acceptable in younger children at risk of severe hypoglycemia. Low HbA1c values are generally associated with a greater risk for hypoglycemia.

The HbA1c level reflects the average blood glucose levels over the previous 3 months and should be measured every 3 months. However, in the DCCT study, HbA1c 7% (53 mmol/mol) corresponded to a higher average blood glucose concentration (measured seven times a day) of 192 mg/dL in the conventionally treated patients compared...
with 163 mg/dL in the intensively treated patients. HbA1c is only one measure of optimal glycemic control, along with preventing hypoglycemia and maximizing quality of life.

The long-term prognosis of children diagnosed with T1D has improved tremendously over the past 20 years, primarily due to better control of blood glucose and blood pressure. While life expectancy is now only 3 years shorter in these patients, compared to the general population, the risk of cardiovascular disease is still four to ten times higher, especially in diabetic women. A checklist of routine tests is presented in Table 35–3.

2. Hypertension—Elevated blood pressure is one of the strongest predictors of both micro- and macrovascular diseases. Treatment of blood pressure is critical in reducing these complications in adults with diabetes and presumably in children and adolescents as well. Blood pressure should be checked and reviewed at each clinic visit. Hypertension is defined as systolic or diastolic blood pressure (measured on at least 3 separate days) above the 95th percentile for the child’s age, sex, and height. Care should be taken to ensure use of the appropriate size cuff in children to avoid inaccurate readings. If elevated blood pressure is confirmed, nondiabetic causes of hypertension should first be excluded. Angiotensin-converting enzyme inhibitors are the first-line agents; if not tolerated well, angiotensin II receptor blockers can be used.

3. Lipid abnormalities—Lipid profiles are generally favorable in children with T1D. The screening for dyslipidemia should commence after the age of 2 years and should be repeated every 5 years thereafter if normal. Good glycemic control should be established in newly diagnosed patients prior to screening, but screening should not be delayed more than 1 year after diagnosis. Children with LDL levels of 130–159 mg/dL (3.4–4.1 mmol/L) should receive dietary and exercise counseling for 6 months, with consideration of pharmacologic therapy if this fails. Statin therapy in addition to diet and lifestyle changes are recommended if LDL is more than 160 mg/dL (4.1 mmol/L). The treatment goals are LDL less than 100 mg/dL (2.6 mmol/L), HDL more than 35 mg/dL (0.9 mmol/L), and triglycerides less than 150 mg/dL (1.7 mmol/L). The use of lipid-lowering drugs in children has been the subject of much discussion. The American Heart Association recommends initiating therapy with statins at the lowest dose at age 10 years in boys, Tanner stage II or higher, and preferably after menarche in girls.

4. Nephropathy—Microalbuminuria is the first clinical manifestation of diabetic kidney disease and may be reversible with diligent glycemic and blood pressure control. Microalbuminuria is defined as: urinary albumin excretion rate between 20 and 200 μg/min or urinary albumin/creatinine ratio 2.5–25 mg/mmol or 30–300 mg/g (spot urine) in males and 3.5–25 mg/mmol in females. Screening for microalbuminuria with a random spot urine sample should occur annually in children once they are 10 years of age and have had diabetes for more than 3–5 years. If values are abnormal, borderline, or increasing, two timed overnight collections should occur and abnormal results should be repeated. The diagnosis of microalbuminuria requires documentation of two out of three abnormal samples over a period of 3–6 months. Once persistent microalbuminuria is confirmed, nondiabetic-related causes of renal disease should be excluded. Following this evaluation, treatment with an ACE inhibitor should be started, even if the blood pressure is normal. Patients should be counseled about the importance of glycemic control and smoking cessation, if applicable. Patients with T2D should have microalbuminuria assessed soon after diagnosis and then annually.

5. Retinopathy—The first dilated ophthalmologic examination should be obtained by an ophthalmologist or optometrist trained in diabetes-specific retinal examination once the child is ≥10 year old and has had diabetes for 3–5 years. The frequency of subsequent examination is generally every 1–2 years, depending on the patient risk profile and advice of the eye care provider. While rare in children, proliferative retinopathy does occur in adolescents with long duration and poor control of diabetes. Laser treatment to coagulate proliferating capillaries prevents bleeding and leakage of blood into the vitreous fluid or behind the retina. This treatment preserves useful vision.

6. Associated autoimmune diseases—Thyroid-stimulating hormone (TSH) level should be measured yearly in all patients. Thyroid peroxidase autoantibody (TPO) is usually the first test to become abnormal in the autoimmune thyroiditis affecting up to 20% of children with T1D. If TPO is positive, we recommend screening with TSH and free T4 every 6–12 months.

Transglutaminase autoantibodies offer a sensitive and specific screening test for celiac disease affecting up to 10% of children with T1D. Risk of celiac disease is most strongly associated with the HLA-DR3/DQ2 haplotype. We recommend routine screening at diagnosis of diabetes and, if negative, retesting every 1–2 year. About half of celiac disease cases develop several years after diagnosis of T1D. Most of the biopsy-confirmed children are “asymptomatic,” but report improved health status upon initiation of gluten-free diet. Untreated celiac disease may lead to severe hypoglycemia, increased bone turnover, and decreased bone mineralization, among many other long-term complications (see Chapter 21).

The 21-hydroxylase autoantibody, a marker of increased risk of Addison disease, is present in approximately 1.3% of patients with type 1 diabetes, although Addison disease develops (usually slowly) in only about one-third of these antibody-positive individuals.
Acute Complications

A. Hypoglycemia

Hypoglycemia (or insulin reaction) is defined as a blood glucose level below 60 mg/dL (3.3 mmol/L). For preschool children, values below 70 mg/dL (3.9 mmol/L) should be cause for concern. The common symptoms of hypoglycemia are hunger, weakness, shakiness, sweating, drowsiness (at an unusual time), headache, and behavioral changes. In the DCCT study, 10% of patients with standard management and 25% of those with intensive insulin management had one or more severe hypoglycemic reactions each year. Children learn to recognize hypoglycemia at different ages but can often report “feeling funny” as young as age 4–5 years. School personnel, sports coaches, and babysitters must be trained to recognize and treat hypoglycemia. If low blood glucose is not treated immediately with simple sugar, the hypoglycemia may result in loss of consciousness and seizures; brain damage or death can occur with prolonged hypoglycemia.

Consistency in daily routine, correct insulin dosage, regular blood glucose monitoring, controlled snacking, compliance of patients and parents, and good education are all important in preventing severe hypoglycemia. In addition, insulin should not be injected prior to getting into a hot tub, bath, or shower as the heat may cause more rapid insulin uptake. The use of insulin analogs has helped to reduce the occurrence of hypoglycemia.

The treatment of mild hypoglycemia involves giving 4 oz of juice, a sugar-containing soda drink, or milk, and waiting 10 minutes. If the blood glucose level is still below 60 mg/dL (3.3 mmol/L), the liquids are repeated. If the glucose level is above 60 mg/dL, solid foods are given. Moderate hypoglycemia, in which the person is conscious but incoherent, can be treated by squeezing one-half tube of concentrated glucose (eg, Insta-Glucose or cake frosting) between the gums and lips and stroking the throat to encourage swallowing.

Families are advised to have glucagon in the home and in their travel pack to treat severe hypoglycemia by giving subcutaneous or intramuscular injections of 0.3 mL (30 units in an insulin syringe) for children younger than age 5 years; 0.5 mL (50 units) to those older than age 5 years; and 1 mL (100 units) to those heavier than 100 lb. Smaller doses of glucagon (2 units + number of units equal to the age of the child, eg, 2 + 10 = 12 units in a 10-year-old) up to a maximum of 15 units can be used to prevent severe hypoglycemia during nondiabetic illness (gastroenteritis, respiratory infections).

Some patients, usually those who have had diabetes for more than 10 years or those tolerating routinely blood glucose 50–80 mg/dL, fail to recognize the symptoms of low blood glucose (hypoglycemic unawareness). For these individuals, glucose control must be liberalized to prevent severe hypoglycemia and CGM should be considered.

B. Sick Day and Diabetic Ketoacidosis

Families must be educated to check blood or urine ketone levels during any illness (including vomiting even once) or any time a fasting blood glucose level is above 240 mg/dL (13.3 mmol/L), or a randomly measured glucose level is above 300 mg/dL (16.6 mmol/L). If moderate or significant ketonuria is detected, or the blood ketone (β-hydroxybutyrate—using the Precision Xtra meter) is above 1.0 mmol/L, the healthcare provider should be called. Usually 10%–20% of the total daily insulin dosage is given subcutaneously as rapid-acting analog or regular insulin every 3–4 hours until blood glucose normalizes. This prevents ketonuria and ketonemia from progressing to ketoacidosis and allows most patients to receive treatment at home by telephone management. Water is the oral fluid of choice if blood glucose is more than 250 mg/dL; at lower levels of glycemia, one should switch to Gatorade/Poweraid or other glucose-containing beverages.

Mild ketonuria/ketonemia secondary to fasting or acute gastrointestinal upset and associated with normal or low blood glucose does not require supplemental insulin treatment. Of note, the brain uses β-hydroxybutyrate as the alternate fuel to glucose in the setting of hypoglycemia. Overtreatment with insulin during a sick day that begins with hyperglycemia and ketosis may lead to loss of consciousness and/or seizures due to severe hypoglycemia.

Acidosis (venous blood pH < 7.30 or bicarbonate <15 mEq/L) is unfortunately still a frequent acute complication in patients with established T1D. Acidosis may occur in those who miss insulin injections, do not check blood or urine ketone levels, or fail to seek help when ketones are elevated. Repeated episodes of ketoacidosis signify that counseling may be indicated, and that a responsible adult must take over the diabetes management. If for any reason this is not possible, a change in the child’s living situation may be necessary.

Treatment of DKA is based on four physiologic principles: (1) restoration of fluid volume; (2) intravenous insulin to inhibit lipolysis and return to glucose utilization; (3) replacement of electrolytes; and (4) correction of acidosis. Mild DKA is defined as a venous blood pH of 7.2–7.3; moderate DKA, a pH of 7.10–7.19; and severe DKA, a pH below 7.10. Patients with severe DKA should be hospitalized in a pediatric intensive care unit, if available. Laboratory tests at the start of treatment should include venous blood pH, glucose, and an electrolyte panel. More severe cases may benefit from determination of blood osmolality, calcium, phosphorus, and urea nitrogen levels. Severe and moderate episodes of DKA generally require hourly determinations of serum glucose, electrolytes, and venous pH levels, whereas these parameters can be measured every 2 hours if the pH level is 7.20–7.30.

1. Restoration of Fluid Volume—Dehydration is judged by estimated loss of body weight, dryness of oral mucous membranes, low blood pressure, and tachycardia.
Initial treatment is with normal saline (0.9%), 10–20 mL/kg during the first hour (can be repeated in severely dehydrated patients during the second hour). The total volume of fluid in the first 4 hours of treatment should not exceed 20–40 mL/kg because of the danger of cerebral edema. After initial expansion, 0.45%–0.9% saline is given at 1.5 times maintenance to replace losses over 24–36 hours. When blood glucose level falls below 250 mg/dL (13.9 mmol/L), 5% dextrose is added to the intravenous fluids. If blood glucose level falls below 120 mg/dL (6.6 mmol/L), 10% dextrose can be added.

2. Inhibition of Lipolysis and Return to Glucose Utilization—Insulin turns off fat breakdown and ketone formation. Regular insulin is given intravenously at a rate of 0.05–0.1 U/kg/h. The insulin solution should be administered by pump and can be made by diluting 30 units of regular insulin in 150 mL of 0.9% saline (1 U/5 mL). If necessary, the insulin dosage can be reduced, but it should not be discontinued before the venous blood pH reaches 7.30 and there is sufficient level of insulin from subcutaneous injections. The half-life of intravenous insulin is 6 minutes, whereas subcutaneous rapid-acting analog insulins take 10–15 minutes, and regular insulin takes 30–60 minutes, to begin activity. We recommend continuing intravenous insulin for at least 30 minutes after the initial subcutaneous insulin injection.

3. Replacement of Electrolytes—In patients with DKA, both sodium and potassium pass into the urine and are depleted. In addition, serum sodium concentrations may be falsely lowered by hyperglycemia, causing water to be drawn into the intravenous space, and by hyperlipidemia if fat replaces some of the water in the serum used for electrolyte analysis. Sodium is usually replaced adequately by the use of 0.45%–0.9% saline in the rehydration fluids. Serum potassium levels may be elevated initially because of inability of potassium to stay in the cell in the presence of acidosis (even though total body potassium is low). Potassium should not be given until the serum potassium level is known to be < 5.0 mEq/L and urine output is confirmed. It is then generally given in replacement fluid at a concentration of 40 mEq/L, with half of the potassium (20 mEq/L) either as potassium acetate or potassium chloride and the other half as potassium phosphate (20 mEq/L). Hypocalcemia can occur if all of the potassium is given as the phosphate salt; hypophosphatemia occurs if none of the potassium is of the phosphate salt.

4. Correction of Acidosis—Acidosis corrects spontaneously as the fluid volume is restored and insulin facilitates aerobic glycolysis and inhibits ketogenesis. Bicarbonate is generally not recommended.

5. Management of Cerebral Edema—Some degree of cerebral edema has been shown by computed tomography scan to occur commonly in DKA. Associated clinical symptoms are rare, unpredictable, and may be associated with demise. Cerebral edema may be related to the degree of dehydration, cerebral hypoperfusion, acidosis, and hyperventilation at the time of presentation. In general, it is recommended that no more than 40 mL/kg of fluids be given in the first 4 hours of treatment and that subsequent fluid replacement not exceed 1.5 times maintenance. Cerebral edema is more common when the serum sodium is noted to be falling rather than rising. Early neurologic signs may include headache, excessive drowsiness, and dilated pupils. Prompt initiation of therapy should include elevation of the head of the bed, mannitol (1 g/kg over 30 minutes), and fluid restriction. If the cerebral edema is not recognized and treated early, over 50% of patients will die or have permanent brain damage.

In summary, modern diabetes care can lead to excellent health outcomes. Tremendous progress in biotechnology (insulin analogs), insulin pumps, and continuous glucose sensing has made the prevention of acute and long-term complications achievable. However, comprehensive and ongoing education of patients and their families remains the foundation of healthy and quality life with diabetes.

Disorders in which single gene defects cause clinically significant blocks in metabolic pathways are called inborn errors of metabolism. Once considered rare, the number of recognized inborn errors has increased dramatically and they are now recognized to affect 1:1500 children. Many of these disorders can be treated effectively. Even when treatment is not available, correct diagnosis permits parents to make informed decisions about future offspring.

The pathology in metabolic disorders usually results from accumulation of enzyme substrate behind a metabolic block or deficiency of a reaction product. In some cases, the accumulated enzyme substrate is diffusible and has adverse effects on distant organs; in other cases, as in lysosomal storage diseases, the substrate primarily accumulates locally. The clinical manifestations of inborn errors vary widely with both mild and severe forms of virtually every disorder. Many patients do not match the classic phenotype because mutations are not identical in different patients, even though they occur in the same gene.

A first treatment strategy is to enhance the reduced enzyme activity. Gene replacement is a long-term goal, but problems of gene delivery to target organs and control of gene action make this an unrealistic option at present. Enzyme-replacement therapy using intravenously administered recombinant enzyme has been developed as an effective strategy in lysosomal storage disorders. Organ transplantation (liver or bone marrow) can provide a source of enzyme for some conditions. Pharmacologic doses of a cofactor such as a vitamin can sometimes be effective in restoring enzyme activity. Residual activity can be increased by pharmacologically promoting transcription (transcriptional upregulation) or by stabilizing the protein product through therapy with chaperones. Alternatively, some strategies are designed to cope with the consequences of enzyme deficiency. Strategies used to avoid substrate accumulation include restriction of precursor in the diet (eg, low-phenylalanine diet for phenylketonuria), avoidance of catabolism, inhibition of an enzyme in the synthesis of the precursor (eg, NTBC in tyrosinemia type I (see Hereditary Tyrosinemia), or removal of accumulated substrate pharmacologically (eg, glycine therapy for isovaleric acidemia) or by dialysis. An inadequately produced metabolite can also be supplemented (eg, glucose administration for glycogen storage disease type I).

Inborn errors can manifest at any time, can affect any organ system, and can mimic many common pediatric problems. This chapter focuses on when to consider a metabolic disorder in the differential diagnosis of common pediatric problems. A few of the more important disorders are then discussed in detail.
in the context of a suspicious history include failure to thrive, microcephaly, rash, jaundice, hypotonia, and hypertonia. Finding an immediate cause of symptoms does not rule out an underlying inborn error. For example, renal tubular acidosis and cirrhosis may be due to an underlying inborn error. Acute crises may be brought on by intercurrent infections in some inborn errors. Some inborn errors suggest a diagnosis of nonaccidental trauma (eg, glutaric acidemia type I) or poisoning (eg, methylmalonic acidemia). In addition, children with inborn errors may be at higher risk for child abuse or neglect because of their frustrating irritability.

**LABORATORY STUDIES**

Table 36–1 lists common clinical and laboratory features of different groups of inborn errors. Table 36–2 lists the most common laboratory tests used to diagnose these diseases and offers suggestions about their use.

Laboratory studies are almost always needed for the diagnosis of inborn errors. Serum electrolytes and pH should be used to estimate anion gap and acid-base status. Serum lactate, pyruvate, and ammonia levels are available in most hospitals, but care is needed in obtaining samples appropriately. Amino acid, acylcarnitine, and organic acid studies must be performed at specialized facilities to ensure accurate analysis and interpretation. An increasing number of inborn errors are diagnosed with DNA sequencing, but interpretation of private mutations, that is, mutations only seen in a particular family, can be problematic. Knowing the causative mutation in the family allows prenatal diagnosis to be done by molecular analysis. This can be done on any material that contains fetal DNA such as chorionic villi, amniotic cells, or fetal blood obtained through umbilical cord blood sampling.

The physician should know what conditions a test can detect and when it can detect them. For example, urine organic acids may be normal in patients with medium-chain acyl-CoA dehydrogenase deficiency or biotinidase deficiency; glycine may be elevated only in cerebrospinal fluid (CSF) in patients with glycine encephalopathy. A result that is normal in one physiologic state may be abnormal in another. For instance, the urine of a child who becomes hypoglycemic upon prolonged fasting should be positive for ketones. In such a child, the absence of ketones in the urine suggests a defect in fatty acid oxidation.

Samples used to diagnose metabolic disease may be obtained at autopsy. Samples must be obtained in a timely fashion and may be analyzed directly or stored frozen until a particular analysis is justified by the results of postmortem examination, new clinical information, or developments in the field. Studies of other family members may help establish the diagnosis of a deceased patient. It may be possible to demonstrate that parents are heterozygous carriers of a particular disorder or that a sibling has the condition.

**COMMON CLINICAL SITUATIONS**

1. **Mental Retardation**

Some inborn errors can cause mental retardation without other distinguishing characteristics. Measurements of serum amino acids, urine organic acids, and serum uric acid should be obtained in every patient with nonspecific mental retardation. Urine screens for mucopolysaccharides and succinylpurines, and serum testing for carbohydrate-deficient glycoproteins are useful because these disorders do not always have specific physical findings. Absent speech can point to disorders of creatine. Abnormalities of the brain detected by magnetic resonance imaging can suggest specific groups of disorders (eg, cortical migrational abnormalities in peroxisomal biogenesis disorders).

2. **Acute Presentation in the Neonate**

Acute metabolic disease in the neonate is most often a result of disorders of protein or carbohydrate metabolism and may be clinically indistinguishable from sepsis. Prominent symptoms include poor feeding, vomiting, altered mental status or muscle tone, jitteriness, seizures, and jaundice. Acidosis, alkalosis, or altered mental status out of proportion to systemic symptoms should increase suspicion of a metabolic disorder. Laboratory measurements should include electrolytes, ammonia, lactate, glucose, blood pH, and urine ketones and reducing substances. Amino acids in CSF should be measured if glycine encephalopathy is suspected. Serum and urine amino acid, urine organic acid, and serum acylcarnitine analysis should be performed urgently. Neonatal cardiomyopathy or ventricular arrhythmias should be investigated with serum acylcarnitine analysis.

3. **Vomiting & Encephalopathy in the Infant or Older Child**

Electrolytes, ammonia, glucose, urine pH, urine reducing substances, and urine ketones should be measured in all patients with vomiting and encephalopathy before any treatment affects the results. Samples for serum amino acids, serum acylcarnitine profile, and urine organic acid analysis should be obtained early. In the presentation of a Reye-like syndrome (ie, vomiting, encephalopathy, and hepatomegaly), amino acids, acylcarnitines, carnitine levels, and organic acids should be assessed immediately. Hypoglycemia with inappropriately low urine or serum ketones suggests the diagnosis of fatty acid oxidation defects.

4. **Hypoglycemia**

Duration of fasting, presence or absence of hepatomegaly, and Kussmaul breathing provide clues to the differential diagnosis of hypoglycemia. Serum insulin, cortisol, and

<table>
<thead>
<tr>
<th>Test</th>
<th>Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Acid-base status</td>
<td>Accurate estimation of anion gap must be possible. Samples for blood gases should be kept on ice and analyzed immediately.</td>
</tr>
<tr>
<td>Blood ammonia</td>
<td>Sample should be kept on ice and analyzed immediately; artifactual elevation common.</td>
</tr>
<tr>
<td>Blood lactic acid and pyruvic acid</td>
<td>Sample should be collected without a tourniquet, kept on ice, and analyzed immediately. Conversion of lactic to pyruvic acid must be prevented. Normal values are for the fasting, rested state, with postprandial values 50% higher.</td>
</tr>
<tr>
<td>Amino acids</td>
<td>Blood and urine should be examined. CSF amino acids should be measured for encephalopathies such as nonketotic hyperglycinemia. Normal values are for the fasting state. Growth of bacteria in urine should be prevented.</td>
</tr>
<tr>
<td>Organic acids</td>
<td>Urine preferred for analysis. Serum or CSF organic acids are rarely indicated and often miss diagnoses.</td>
</tr>
<tr>
<td>Carnitine and acylcarnitine profile</td>
<td>Blood or plasma may be analyzed for total, free, and esterified carnitine; normal values are for the healthy, nonfasted state. Acylcarnitine profile in blood identifies compounds esterified to carnitine. Rarely urine and bile studies may be needed. Profiling in cultured fibroblasts after fat loading can be helpful in diagnosis of certain conditions.</td>
</tr>
<tr>
<td>Urine mucopolysaccharides</td>
<td>Variations in urine protein concentration may cause errors in screening tests. Diagnosis requires knowing which mucopolysaccharides are increased. Some patients with Morquio disease and many with Sanfilippo disease do not have abnormal mucopolysacchariduria.</td>
</tr>
<tr>
<td>Enzyme assays</td>
<td>Specific assays must be requested. Exposure to heat may cause loss of enzyme activity. Enzyme activity in whole blood may become normal after transfusion or vitamin therapy. Leukocyte or fibroblast pellets should be kept frozen prior to assays. Fibroblasts may be grown from skin biopsies taken up to 72 h after death. Tissues such as muscle, liver, and kidney should be taken as soon as possible after death (&lt; 2 h), frozen immediately, and kept at −70°C until assayed.</td>
</tr>
</tbody>
</table>

CSF, cerebrospinal fluid.
growth hormone should be obtained on presentation. Urine ketones, urine organic acids, plasma lactate, serum acylcarnitine profile, carnitine levels, ammonia, triglycerides, and uric acid should be measured. Ketone body production is usually not efficient in the neonate, and ketonuria in a hypoglycemic or acidic neonate suggests an inborn error. In the older child, inappropriately low urine ketone levels suggest an inborn error of fatty acid oxidation. Assessment of ketone generation requires simultaneous measurements of quantitative serum 3-hydroxybutyrate, acetoacetate, and free fatty acids in relation to a sufficient duration of fasting and age. Metabolites obtained during the acute episode can be very helpful and avoid the need for a formal fasting test.

5. Hyperammonemia

Symptoms of hyperammonemia may appear and progress rapidly or insidiously. Decreased appetite, irritability, and behavioral changes appear first with vomiting, ataxia, lethargy, seizures, and coma appearing as ammonia levels increase. Tachypnea inducing respiratory alkalosis due to a direct effect on respiratory drive is characteristic. Physical examination cannot exclude the presence of hyperammonemia, and serum ammonia should be measured whenever hyperammonemia is possible. Severe hyperammonemia may be due to urea cycle disorders, organic acidemias, or fatty acid oxidation disorders (such as carnitine-acylcarnitine translocase deficiency) or, in the premature infant, transient hyperammonemia of the newborn. The cause can usually be ascertained by measuring quantitative serum amino acids (eg, citrulline), plasma carnitine and acylcarnitine esters, and urine organic acids and orotic acid. Respiratory alkalosis is usually present in urea cycle defects and transient hyperammonemia of the newborn, while acidosis is characteristic of hyperammonemia due to organic acidemias.

6. Acidosis

Inborn errors may cause chronic or acute acidosis at any age, with or without an increased anion gap. Inborn errors should be considered when acidosis occurs with recurrent vomiting or hyperammonemia and when acidosis is out of proportion to the clinical status. Acidosis due to an inborn error can be difficult to correct. The main causes of anion gap metabolic acidosis are lactic acidosis, ketoacidosis (including abnormal ketone body production such as in β-ketothiolase deficiency), methylmalonic aciduria or other organic acidurias, intoxication (ethanol, methanol, ethylene glycol, and salicylate), and uremia. Causes of non–anion gap metabolic acidosis include loss of base in diarrhea or renal tubular acidosis (isolated renal tubular acidosis or renal Fanconi syndrome). If renal bicarbonate loss is found, a distinction must be made between isolated renal tubular acidosis and a more generalized renal tubular disorder or renal Fanconi syndrome by testing for renal losses of phosphorus and amino acids. Inborn errors associated with renal tubular acidosis or renal Fanconi syndrome include cystinosis, tyrosinemia type I, carnitine palmitoyltransferase I, galactosemia, hereditary fructose intolerance, Lowe syndrome, and mitochondrial diseases. Serum glucose and ammonia levels and urinary pH and ketones should be examined. Samples for amino acids and organic acids should be obtained at once and may be evaluated immediately or frozen for later analysis, depending on how strongly an inborn error is suspected. It is useful to test blood lactate and pyruvate levels in the chronically acidic patient even if urine organic acid levels are normal. Lactate and pyruvate levels are difficult to interpret in the acutely ill patient, but in the absence of shock, high levels of lactic acid suggest primary lactic acidosis.

MANAGEMENT OF METABOLIC EMERGENCIES

Patients with severe acidosis, hypoglycemia, and hyperammonemia may be very ill; initially mild symptoms may worsen quickly, and coma and death may ensue within hours. With prompt and vigorous treatment, however, patients can recover completely, even from deep coma. All oral intake should be stopped. Sufficient glucose should be given intravenously to avoid or minimize catabolism in a patient with a known inborn error who is at risk for crisis. Most conditions respond favorably to glucose administration, although a few (eg, primary lactic acidosis due to pyruvate dehydrogenase deficiency) do not. After exclusion of fatty acid oxidation disorders, immediate institution of intravenous fat emulsions (eg, intralipid) can provide crucial caloric input. Severe or increasing hyperammonemia should be treated pharmacologically or with dialysis (see Disorders of the Urea Cycle), and severe acidosis should be treated with bicarbonate. More specific measures can be instituted when a diagnosis is established.

NEWBORN SCREENING

Criteria for screening newborns for a disorder include its frequency, its consequences if untreated, the ability of therapy to mitigate consequences, the cost of testing, and the cost of treatment. With the availability of tandem mass spectrometry, newborn screening has expanded greatly to now include 20 core conditions and multiple secondary conditions screened by most states. In general, amino acidopathies, organic acidurias, and disorders of fatty acid oxidation are the disorders for which screening now occurs. Most states also screen for hypothyroidism, congenital adrenal hyperplasia, hemoglobinopathies, biotinidase deficiency, galactosemia, and cystic fibrosis. Screening for severe combined immune deficiency has been recently added. Screening should occur for all infants between 24 and 72 hours of life or before hospital discharge.
Some screening tests measure a metabolite (eg, phenylalanine) that becomes abnormal with time and exposure to diet. In such instances, the disease cannot be detected reliably until intake of the substrate is established. Other tests measure enzyme activity and can be performed at any time (eg, for biotinidase deficiency). Transfusions may cause false-negative results in this instance, and exposure of the sample to heat may cause false-positive results. Technologic advances have extended the power of newborn screening but have brought additional challenges. For example, although tandem mass spectrometry can detect many more disorders in the newborn period, consensus on diagnosis and treatment for some conditions is still under development.

Screening tests are not diagnostic, and diagnostic tests must be undertaken when an abnormal screening result is obtained. Further, because false-negative results occur, a normal newborn screening test does not rule out a condition.

The appropriate response to an abnormal screening test depends on the condition in question and the predictive value of the test. For example, when screening for galactosemia by enzyme assay, complete absence of enzyme activity is highly predictive of classic galactosemia. Failure to treat may rapidly lead to death. In this case, treatment must be initiated immediately while diagnostic studies are pending. In phenylketonuria, however, a diet restricted in phenylalanine is harmful to the infant whose screening test is a false-positive, while diet therapy produces an excellent outcome in the truly affected infant if treatment is established within the first weeks of life. Therefore, treatment for phenylketonuria should only be instituted when the diagnosis is confirmed. Physicians should review American College of Medical Genetics recommendations, state laws and regulations, and consult with their local metabolic center to arrive at appropriate strategies for each hospital and practice.

Wilcken B: Newborn screening: how are we traveling, and where should we be going? J Inherit Metab Dis 2011;34(3):569 [PMID: 21499716].

**DISORDERS OF CARBOHYDRATE METABOLISM**

**GLYCOGEN STORAGE DISEASES**

- Types 0, I, III, VI, and IX manifest with hypoglycemia in infants.
- Types II, V, and VII manifest with rhabdomyolysis or muscle weakness.
- Types IV and IX manifest with hepatic cirrhosis.

Glycogen is a highly branched polymer of glucose that is stored in liver and muscle. Different enzyme defects affect its biosynthesis and degradation. The hepatic forms of the glycogenoses cause growth failure, hepatomegaly, and severe fasting hypoglycemia. They include glucose-6-phosphatase deficiency (type I; von Gierke disease), debrancher enzyme deficiency (type III), hepatic phosphorylase deficiency (type VI), and phosphorylase kinase deficiency (type IX), which normally regulates hepatic phosphorylase activity. Glycogen synthase deficiency (GSD0) causes hypoglycemia usually after about 12 hours fasting, and can cause mild postprandial hyperglycemia and hyperlactatemia. There are two forms of glucose-6-phosphatase deficiency: in type Ia, the catalytic glucose-6-phosphatase is deficient, and in type Ib, the glucose-6-phosphate transporter is deficient. The latter form also has neutropenia. Glycogenosis type IV, brancher enzyme deficiency, usually presents with progressive liver cirrhosis, as do some rare forms of phosphorylase kinase deficiency.

The myopathic forms of glycogenosis affect skeletal muscle. Skeletal myopathy with weakness or rhabdomyolysis may be seen in muscle phosphorylase deficiency (type V), phosphofructokinase deficiency (type VII), and acid maltase deficiency (type II; Pompe disease). The infantile form of Pompe disease also has hypertrophic cardiomyopathy and macroglossia. The gluconeogenic disorder fructose-1,6-bisphosphatase deficiency presents with major lactic acidosis and delayed hypoglycemia on fasting.
GALACTOSEMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Severely deficient neonates present with vomiting, jaundice, and hepatomegaly on initiation of lactose-containing feedings.
- Renal Fanconi syndrome, cataracts of the ocular lens, hepatic cirrhosis, and sepsis occur in untreated children.
- Delayed, apraxic speech and ovarian failure occur frequently even with treatment. Developmental delay, tremor, and ataxia occur less frequently.

Classic galactosemia is caused by almost total deficiency of galactose-1-phosphate uridyltransferase. Accumulation of galactose-1-phosphate causes hepatic parenchymal disease and renal Fanconi syndrome. Onset of the severe disease is marked in the neonate by vomiting, jaundice (both direct and indirect), hepatomegaly, and rapid onset of liver insufficiency after initiation of milk feeding. Hepatic cirrhosis is progressive. Without treatment, death frequently occurs within a month, often from Escherichia coli sepsis. Cataracts usually develop within 2 months in untreated cases but usually reverse with treatment. With prompt institution of a galactose-free diet, the prognosis for survival without liver disease is excellent. Even when dietary restriction is instituted early, patients with galactosemia are at increased risk for speech and language deficits and ovarian failure. Some patients develop progressive mental retardation, tremor, and ataxia. Milder variants of galactosemia with better prognosis exist.

The disorder is autosomal recessive with an incidence of approximately 1:40,000 live births.

Diagnosis

Initial tests include glucose, lactate, triglycerides, cholesterol, uric acid, transaminases, and creatine kinase. Functional testing includes responsiveness of blood glucose and lactate to fasting; for myopathic forms, an ischemic exercise test is helpful. Most glycogenoses can now be diagnosed by molecular analysis, including next-generation panels. Other diagnostic studies include enzyme assays of leukocytes, fibroblasts, liver, or muscle. Disorders diagnosable from analysis of red or white blood cells include deficiency of debrancher enzyme (type III) and phosphorylase kinase (type IX). Pompe disease can usually be diagnosed by assaying acid maltase in a blood spot with confirmation in fibroblasts.

Treatment

Treatment is designed to prevent hypoglycemia and avoid secondary metabolite accumulations such as elevated lactate in glycogenosis type I. In the most severe hepatic forms, the special diet must be strictly monitored with restriction of free sugars and measured amounts of uncooked cornstarch, which slowly releases glucose in the intestinal lumen. Good results have been reported following continuous nighttime carbohydrate feeding or uncooked cornstarch therapy. Late complications even after years of treatment include focal segmental glomerulosclerosis, hepatic adenoma or carcinoma, and gout. Enzyme-replacement therapy in Pompe disease corrects the cardiomyopathy, but the response in skeletal myopathy is variable with optimal results seen in patients treated early and who have mutations that allow formation of some residual protein which is detected as cross-reacting material on Western blotting. Immunomodulation is used for patients whose treatment response declines due to antibodies to the recombinant enzyme.

Bhattacharya K: Dietary dilemmas in the management of glycogen storage disease type I. J Inherit Metab Dis 2011;34:621 [PMID: 21491105].
Patient and parent support group website with useful information for families: http://www.agsdus.org.

When the diagnosis is suspected, galactose-1-phosphate uridyltransferase should be assayed in erythrocytes. Blood transfusions give false-negative results and sample deterioration false-positive results.

Newborn screening by demonstrating enzyme deficiency in red cells with the Beutler test or by demonstrating increased serum galactose allows timely institution of treatment.

**Treatment**

A galactose-free diet should be instituted as soon as the diagnosis is made. Compliance with the diet must be monitored by following galactose-1-phosphate levels in red blood cells. Appropriate diet management requires not only the exclusion of milk but an understanding of the galactose content of foods. Avoidance of galactose should be lifelong with appropriate calcium replacement, intake of which tends to be low due to the restriction of dairy products.

Diagnosis is made by sequencing the *HFI* gene. An alternative method for diagnosis is enzyme assay of fructose-1-phosphate aldolase in liver biopsy.

**Treatment**

Treatment consists of strict dietary avoidance of fructose. Vitamin supplementation is usually needed. Drugs and vitamins dispensed in a sucrose base should be avoided. Treatment monitoring can be done with transferrin glycoform analysis. If diet compliance is poor, physical growth retardation may occur. Growth will resume when more stringent dietary restrictions are reinstated. If the disorder is recognized early, the prospects for normal development are good. As affected individuals grow up, they may recognize the association of nausea and vomiting with ingestion of fructose-containing foods and selectively avoid them.

**Disorders of Energy Metabolism**

The most common disorders of central mitochondrial energy metabolism are pyruvate dehydrogenase deficiency and deficiencies of respiratory chain components. Disorders of the Krebs cycle include deficiencies in fumarase, 2-ketoglutarate dehydrogenase, and succinyl-CoA ligase. In many, but not in all, patients lactate is elevated in either blood or CSF. In pyruvate dehydrogenase deficiency, the lactate-pyruvate ratio is normal, whereas in respiratory chain disorders the ratio is often increased. Care must be taken to distinguish an elevated lactate level that is due to these conditions (called primary lactic acidoses) from elevated lactate that is a consequence of hypoxia, ischemia, or sampling problems. Table 36-3 lists some causes of primary lactic acidosis.

Patients with a defect in the pyruvate dehydrogenase complex often have agenesis of the corpus callosum or Leigh syndrome (lesions in the globus pallidus, dentate nucleus, and periaqueductal gray matter). They can have mild facial dysmorphism. Recurrent altered mental status, recurrent ataxia, and recurrent acidosis are typical of many disturbances of pyruvate metabolism. The most common genetic defect is in the X-linked E1-α component, with males carrying milder mutations and females carrying severe mutations leading to periventricular cystic brain lesions.

The respiratory chain disorders are frequent (1:5000) and involve a heterogenous group of genetic defects that produce a variety of clinical syndromes (now > 50) of varying severity and presentation. The disorders can affect multiple organs. The following set of symptoms (not intended as a comprehensive listing) can indicate a respiratory chain disorder:
Table 36–3. Causes of primary lactic acidosis in childhood.

**Abnormalities of gluconeogenesis**
- Pyruvate carboxylase deficiency
  - Isolated
  - Biotinidase deficiency
  - Holocarboxylase synthetase deficiency
  - Fructose-1,6-diphosphatase deficiency
  - Glucose-6-phosphatase deficiency (von Gierke disease)

**Defects in the mitochondrial respiratory chain**
- Complex I deficiency
- Complex IV deficiency (cytochrome c oxidase deficiency; frequent cause of Leigh disease)
- Complex V (ATPase) deficiency (frequent cause of Leigh disease)
- Complex II deficiency
- Complex III deficiency
- Combined deficiencies: due to defects in mitochondrial DNA maintenance (deletions or depletion) or in mitochondrial translation (eg, mitochondrial tRNA defects)
- Coenzyme Q10 deficiency
- Other respiratory chain disorders

**Defects in the Krebs cycle**
- Succinyl-CoA ligase deficiency

1. General: Failure to thrive
2. Brain: Progressive neurodegeneration, Leigh syndrome, myoclonic seizures, brain atrophy, and subcortical leukodystrophy
3. Eye: Optic neuropathy, retinitis pigmentosa, progressive external ophthalmoplegia, and cataracts
4. Ears: Nerve deafness
5. Muscle: Myopathy with decreased endurance or rhabdomyolysis
7. Endocrine: Diabetes mellitus and hypoparathyroidism
8. Intestinal: Pancreatic or liver insufficiency or pseudoobstruction
9. Skin: Areas of hypopigmentation
10. Heart: Cardiomyopathy, conduction defects, and arrhythmias

Respiratory chain disorders are among the more common causes of static, progressive, or self-limited neurodevelopmental problems in children. Patients may present with nonspecific findings such as hypotonia, failure to thrive, or renal tubular acidosis, or with more specific features such as ophthalmoplegia or cardiomyopathy. Symptoms are often combined in recognizable clinical syndromes with ties to specific genetic causes. Ragged red fibers and mitochondrial abnormalities may be noted on histologic examination of muscle. Thirteen of the more than 100 genes that control activity of the respiratory chain are part of the mitochondrial genome. Therefore, inheritance of defects in the respiratory chain may be mendelian or maternal.

**Diagnosis**

Pyruvate dehydrogenase deficiency is diagnosed by enzyme assay in leukocytes or fibroblasts. Confirmation can be obtained by molecular analysis. Diagnosis of respiratory chain disorders is based on a convergence of clinical, biochemical, morphologic, enzymatic, and molecular data. Classic pathologic features of mitochondrial disorders are the accumulation of mitochondria, which produces ragged red fibers in skeletal muscle biopsy, and abnormal mitochondrial shapes and inclusions inside mitochondria on electron microscopy. However, these findings are only present in 5% of children. Enzyme analysis on skeletal muscle or liver tissue is complicated by an overlap between normal and affected range. Blue native polyacrylamide gel electrophoresis (PAGE) analyzes the assembly of the respiratory chain enzyme complexes. Mitochondrial DNA (mtDNA) analysis in blood or tissue may identify a diagnostic mutation. A rapidly increasing number of nuclear genes (now > 100) causing respiratory chain defects are recognized. Children with defects in mtDNA maintenance (such as mtDNA polymerase γ, POLG1 gene) often present with liver disease and neurodegeneration and are diagnosed by sequencing the causative nuclear genes. Next-generation sequencing of panels of genes or exome sequencing is increasingly used due to the large number of genes involved, but functional testing is often required for confirmation of the pathogenicity of identified mutations. Although diagnostic criteria have been published, the cause of respiratory chain defects still cannot be defined in many patients. In some instances, the genetics and prognosis may be clear, but in many cases neither prognosis nor genetic risk can be predicted. Because of the high complexity of this group of disorders, many patients require a high degree of expertise and multiple studies to arrive at a final diagnosis.

**Treatment**

A ketogenic diet is useful in pyruvate dehydrogenase deficiency. In rare patients with primary coenzyme Q deficiency, coenzyme Q treatment is very effective. Other treatments are of theoretical value, with little data on efficacy. Thiamine and lipoic acid have been tried in patients with pyruvate
dehydrogenase complex deficiencies, and coenzyme Q and riboflavin have been helpful in some patients with respiratory chain defects. Dichloroacetic acid has limited clinical response in pyruvate dehydrogenase deficiency and has adverse effects. Avoidance of catabolism and of medications that impair mitochondrial function is an important component of treating patients with respiratory chain defects. Transcriptional upregulation in partial deficiencies of nuclear origin and new antioxidants such as EPI-743 offer new hope for the treatment of respiratory chain defects.

DISORDERS OF THE UREA CYCLE

Ammonia is derived from the catabolism of amino acids and is converted to an amino group in urea by enzymes of the urea cycle. Patients with severe defects (often those enzymes early in the urea cycle) usually present in infancy with severe hyperammonemia, vomiting, and encephalopathy, which is rapidly fatal. Patients with milder genetic defects may present with vomiting, encephalopathy, or liver failure after increased protein ingestion or infection. Although defects in argininosuccinic acid synthetase (citrullinemia) and argininosuccinic acid lyase (argininosuccinic acidemia) may cause severe hyperammonemia in infancy, the usual clinical course is chronic with mental retardation. Ornithine transcarbamylase deficiency is X-linked; the others are autosomal recessive. Age at onset of symptoms varies with residual enzyme activity, protein intake, growth, and stresses such as infection. Even within a family, males with ornithine transcarbamylase deficiency may differ by decades in the age of symptom onset. Many female carriers of ornithine transcarbamylase deficiency have protein intolerance. Some develop migraine-like symptoms after protein loads, and others develop potentially fatal episodes of vomiting and encephalopathy after protein ingestion, infections, or during labor and delivery. Trichorrhexis nodosa is common in patients with argininosuccinic aciduria.

Diagnosis

Blood ammonia should be measured in any acutely ill newborn in whom a cause is not obvious. In urea cycle defects, early hyperammonemia is associated with hyperventilation and respiratory alkalosis. Serum citrulline is low or undetectable in carbamoyl phosphate synthetase and ornithine transcarbamylase deficiency, high in argininosuccinic acidemia, and very high in citrullinemia. Large amounts of argininosuccinic acid are found in the urine of patients with argininosuccinic acidemia. Urine orotic acid is increased in infants with ornithine transcarbamylase deficiency. Citrullinemia and argininosuccinic acidemia can be diagnosed in utero by appropriate enzyme assays in uncultured chorionic villus sample (CVS) material or in amniocytes, but carbamoyl phosphate synthetase and ornithine transcarbamylase deficiency can be diagnosed in utero only by molecular methods.

Treatment

During treatment of acute hyperammonemic crisis, protein intake should be stopped, and glucose and lipids should be given to reduce endogenous protein breakdown from catabolism. Careful administration of essential amino acids facilitates protein anabolism. Arginine is given intravenously. It is an essential amino acid for patients with urea cycle defects and increases the excretion of waste nitrogen in citrullinemia and argininosuccinic acidemia. Sodium benzoate and sodium phenylacetate are given intravenously to increase excretion of nitrogen as hippuric acid and phenylacetylglutamine. Additionally, hemodialysis or hemofiltration is indicated for severe or persistent hyperammonemia, as is usually the case in the newborn. Peritoneal dialysis and exchange transfusion are ineffective. Long-term treatment includes low-protein diet, oral administration of arginine or citrulline, and sodium benzoate or sodium phenylbutyrate (a prodrug of sodium phenylacetate). Symptomatic heterozygous female carriers of ornithine transcarbamylase deficiency should also receive such treatment. Liver transplantation may be curative and is indicated for patients with severe disorders.

The outcome of urea cycle disorders depends on the genetic severity of the condition (residual activity) and the severity and prompt treatment of hyperammonemic episodes.
Brain damage depends on the duration and the degree of elevation of ammonia (and glutamine). Many patients with urea cycle defects, no matter what the enzyme defect, develop permanent neurologic and intellectual impairments, with cortical atrophy and ventricular dilation seen on computed tomographic scan. Rapid identification and treatment of the initial hyperammonemic episode improve outcome.

Patient and parent support group website with useful information for families: http://www.nucdf.org.

PHENYLKETONURIA & THE HYPERPHENYLALANINEMIAS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Mental retardation, hyperactivity, seizures, light complexion, and eczema characterize untreated patients.
- Newborn screening for elevated serum phenylalanine identifies most infants.
- Disorders of cofactor metabolism also produce elevated serum phenylalanine level.
- Early diagnosis and treatment with phenylalanine-restricted diet prevents mental retardation.

Probably the best-known disorder of amino acid metabolism is the classic form of phenylketonuria caused by decreased activity of phenylalanine hydroxylase, the enzyme that converts phenylalanine to tyrosine. In classic phenylketonuria, there is little or no phenylalanine hydroxylase activity. In the less severe hyperphenylalaninemia there may be significant residual activity. Rare variants can be due to deficiency of dihydropteridine reductase or defects in biopterin synthesis.

Phenylketonuria is an autosomal recessive trait, with an incidence in Caucasians of approximately 1:10,000 live births. On a normal neonatal diet, affected patients develop hyperphenylalaninemia. Patients with untreated phenylketonuria exhibit severe mental retardation, hyperactivity, seizures, a light complexion, and eczema.

Success in preventing severe mental retardation in phenylketonuric children by restricting phenylalanine starting in early infancy led to screening programs to detect the disease early. Because the outcome is best when treatment is begun in the first month of life, infants should be screened during the first few days. A second test is necessary when newborn screening is done before 24 hours of age, and should be completed by the third week of life.

Diagnosis & Treatment

The diagnosis of phenylketonuria is based on finding elevated serum phenylalanine and an elevated phenylalanine/tyrosine ratio in a child on a normal diet. The condition must be differentiated from other causes of hyperphenylalaninemia by examining pterins in urine and dihydropteridine reductase activity in blood.

Determination of carrier status and prenatal diagnosis of phenylketonuria or pterin defects is possible using molecular methods.

A. Phenylalanine Hydroxylase Deficiency: Classic Phenylketonuria and Hyperphenylalaninemia

In phenylketonuria, serum phenylalanine levels are persistently elevated above 1200 μM (20 mg/dL) on a regular diet, with normal or low serum levels of tyrosine, and normal pterins. Poor phenylalanine tolerance persists throughout life. Treatment to decrease phenylalanine levels is always indicated. Hyperphenylalaninemia is diagnosed in infants whose serum phenylalanine levels are usually 240–1200 μM (4–20 mg/dL), and pterins are normal while receiving a normal protein intake. Treatment to reduce phenylalanine levels is indicated if phenylalanine levels consistently exceed 600 μM (10 mg/dL). In contrast, in the rare case of transient hyperphenylalaninemia, serum phenylalanine levels are elevated early but progressively decline toward normal. Dietary restriction is only temporary, if required at all.

Treatment of all forms of phenylketonuria is aimed at maintaining phenylalanine levels less than 360 μM (6 mg/dL). Treatment can consist of dietary restriction of phenylalanine, increasing enzyme activity with pharmacologic doses of R-tetrahydrobiopterin, or new methods to interfere with phenylalnine absorption or to breakdown phenylalanine.
Dietary restriction of phenylalanine intake to amounts that permit normal growth and development is the most common therapy and results in good outcome if instituted in the first month of life and carefully maintained. Metabolic formulas deficient in phenylalanine are available but must be supplemented with normal milk and other foods to supply enough phenylalanine to permit normal growth and development. Serum phenylalanine concentrations must be monitored frequently while ensuring that growth, development, and nutrition are adequate. This monitoring is best done in experienced clinics. Children with classic phenylketonuria who receive treatment promptly after birth and achieve phenylalanine and tyrosine homeostasis will develop well physically and can be expected to have normal or near-normal intellectual development.

Phenylalanine restriction should continue throughout life. Patients who discontinued diet after treatment for several years have developed subtle changes in intellect and behavior, and risk neurologic damage. Counseling should be given during adolescence particularly to girls about the risk of maternal phenylketonuria (see as follows), and women’s diets should be monitored closely prior to conception and throughout pregnancy. Late treatment may still be of benefit in reversing behaviors such as hyperactivity, irritability, and distractibility, but it does not reverse the mental retardation.

Treatment with R-tetrahydrobiopterin results in improved phenylalanine tolerance in up to 50% of patients with a deficiency in phenylalanine hydroxylase. The best results and the most frequent responsiveness are seen in patients with hyperphenylalaninemia. Provision of high doses of large neutral amino acids results in a moderate reduction in phenylalanine and is used as an adjunctive treatment in some adults with phenylketonuria. Treatment trials with pegylated phenylalanine ammonia lyase administration to decrease phenylalanine levels show promise.

B. Biopterin Defects: Dihydropteridine Reductase Deficiency and Defects in Biopterin Biosynthesis

In these patients, serum phenylalanine levels vary. The pattern of pterin metabolites is abnormal. Clinical findings include myoclonus, tetraplegia, dystonia, oculogyric crises, and other movement disorders. Seizures and psychomotor regression occur even with diet therapy, probably because the enzyme defect also causes neuronal deficiency of serotonin and dopamine. These deficiencies require treatment with levodopa, carbidopa, 5-hydroxytryptophan, and folic acid. Tetrahydrobiopterin may be added for some biopterin synthesis defects.

C. Tyrosinemia of the Newborn

Serum phenylalanine levels are lower than those associated with phenylketonuria and are accompanied by marked hypertyrosinemia. Tyrosinemia of the newborn usually occurs in premature infants and is due to immaturity of 4-hydroxyphenylpyruvic acid oxidase, resulting in increase in tyrosine and its precursor phenylalanine. The condition resolves spontaneously within 3 months, almost always without sequelae.

D. Maternal Phenylketonuria

Offspring of phenylketonuric mothers may have transient hyperphenylalaninemia at birth. Elevated maternal phenylalanine causes mental retardation, microcephaly, growth retardation, and often congenital heart disease or other malformations in the offspring. The risk to the fetus is lessened considerably by maternal phenylalanine restriction with maintenance of phenylalanine levels below 360 μM (6 mg/dL) throughout pregnancy and optimally started before conception.

HEREDITARY TYROSINEMIA

Type I hereditary tyrosinemia is an autosomal recessive condition caused by deficiency of fumarylacetoacetase. It presents with acute or progressive hepatic parenchymal damage with elevated α-fetoprotein, renal tubular dysfunction with generalized aminoaciduria, hypophosphatemic rickets, or neuronopathic crises. Tyrosine and methionine are increased in blood and tyrosine metabolites and δ-aminolevulinic acid in urine. The key diagnostic metabolite is elevated succinylacetone in urine. Liver failure may be rapidly fatal in infancy or somewhat more chronic, with
a high incidence of liver cell carcinoma in long-term survivors. Tyrosinemia type II presents with corneal ulcers and keratotic lesions on palms and soles and very high serum tyrosine levels (> 600 μM).

**Diagnosis**

Similar clinical and biochemical findings may occur in other liver diseases such as galactosemia and hereditary fructose intolerance. Increased succinylacetone occurs only in fumarylacetoacetase deficiency and is diagnostic. Diagnosis is confirmed by mutation analysis or by enzyme assay in liver tissue. Prenatal diagnosis is possible. Tyrosinemia type II is diagnosed by molecular methods.

**Treatment**

A diet low in phenylalanine and tyrosine ameliorates liver disease, but it does not prevent carcinoma development. Pharmacologic therapy to inhibit the upstream enzyme 4-hydroxyphenylpyruvate dehydrogenase using 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC) decreases the production of toxic metabolites, maleylacetoacetate and fumarylacetoacetate. It improves the liver disease and renal disease, prevents acute neuronopathic attacks, and greatly reduces the risk of hepatocellular carcinoma. Liver transplantation is effective therapy. Tyrosinemia type II symptoms respond well to treatment with dietary tyrosine restriction.

**MAPLE SYRUP URINE DISEASE**

**(BRANCHED-CHAIN KETOACIDURIA)**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Typical presentation is infantile encephalopathy.

Maple syrup urine disease is due to deficiency of the enzyme-catalyzing oxidative decarboxylation of the branched-chain keto acid derivatives of leucine, isoleucine, and valine. Accumulated keto acids of leucine and isoleucine cause the characteristic odor. Only leucine and its corresponding keto acid have been implicated in causing central nervous system (CNS) dysfunction. Many variants of this disorder have been described, including mild, intermittent, and thiamine-dependent forms. All are autosomal recessive traits.

Patients with classic maple syrup urine disease are normal at birth, but after about 1 week they develop feeding difficulties, coma, and seizures. Unless diagnosis is made and dietary restriction of branched-chain amino acids is begun, most will die in the first month of life. Nearly normal growth and development may be achieved if treatment is begun before about age 10 days, which is facilitated by newborn screening.

**Diagnosis**

Amino acid analysis shows marked elevation of branched-chain amino acids including alloisoleucine, a diagnostic transamination product of the keto acid of isoleucine. Urine organic acids demonstrate the characteristic keto acids. The magnitude and consistency of metabolite changes are altered in mild and intermittent forms. Prenatal diagnosis is possible by enzyme assay in cultured amniocytes or chorionic villi, and by molecular analysis of the mutation is known.

**Treatment**

Dietary leucine restriction and avoidance of catabolism are the cornerstones of treatment. Infant formulas deficient in branched-chain amino acids must be supplemented with normal foods to supply enough branched-chain amino acids to permit normal growth. Serum levels of branched-chain amino acids must be monitored frequently to deal with changing protein requirements. Acute episodes must be aggressively treated to prevent catabolism and negative nitrogen balance. Very high leucine levels may require hemodialysis.

Patient and parent support group website with useful information for families: http://www.msud-support.org.

**HOMOCYSTINURIA**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Consider in a child of any age with a marfanoid habitus, dislocated lenses, or thrombosis.

- Newborn screening allows early diagnosis and treatment resulting in a normal outcome.
Homocystinuria is most often due to deficiency of cystathionine β-synthase (CBS), but may also be due to deficiency of methylenetetrahydrofolate reductase (MTHFR) or to defects in the biosynthesis of methyl-B₁₂, the coenzyme for methionine synthase. All inherited forms of homocystinuria are autosomal recessive traits.

About 50% of patients with untreated CBS deficiency are mentally retarded, and most have arachnodactyly, osteoporosis, and a tendency to develop dislocated lenses and thromboembolic phenomena. Mild variants of CBS deficiency present with thromboembolic events. Patients with severe remethylation defects usually exhibit failure to thrive and a variety of neurologic symptoms, including brain atrophy, microcephaly, and seizures in infancy and early childhood. Very mild elevations of homocysteine, such as caused by a polymorphism of MTHFR resulting in a heat sensitive protein, are increasingly recognized as a factor in the etiology of vascular disease leading to myocardial infarction and stroke.

**Diagnosis**

Diagnosis is made by demonstrating elevated total serum homocysteine or by identifying homocystinuria in a patient who is not severely deficient in vitamin B₁₂. Serum methionine levels are usually high in patients with CBS deficiency and often low in patients with remethylation defects. Cystathionine levels are low in CBS deficiency. When the remethylation defect is due to deficiency of methyl-B₁₂ megaloblastic anemia or hemolytic uremic syndrome may be present and an associated deficiency of adenosyl-B₁₂ may cause methylmalonic aciduria. Mutation analysis or studies of cultured fibroblasts can make a specific diagnosis.

**Treatment**

About 50% of patients with CBS deficiency respond to large oral doses of pyridoxine. Pyridoxine nonresponders are treated with dietary methionine restriction and oral administration of betaine, which increases methylation of homocysteine to methionine and improves neurologic function. Early treatment prevents mental retardation, lens dislocation, and thromboembolic manifestations, which justifies the screening of newborn infants. Large doses of vitamin B₁₂ (e.g., 1–5 mg hydroxocobalamin administered daily intramuscularly or subcutaneously) are indicated in some patients with defects in cobalamin metabolism.

**NONKETOTIC HYPERGLYCINEMIA**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Severely affected newborns have apnea, hypotonia, lethargy, myoclonic seizures, and hiccups.
- Mental and motor retardation in most patients.
- Mildly affected children have developmental delay, hyperactivity, mild chorea, and seizures.
- Electroencephalography (EEG) shows burst suppression.
- CSF glycine is elevated.

Inherited deficiency of various subunits of the glycine cleavage enzyme causes nonketotic hyperglycinemia, also called glycine encephalopathy. Glycine accumulation in the brain disturbs neurotransmission of the glycinergic receptors and the N-methyl-d-aspartate type of glutamate receptor. In its most severe form, the condition presents in the newborn as hypotonia, lethargy proceeding to coma, myoclonic seizures, and hiccups, with a burst suppression pattern on EEG. Respiratory depression may require ventilator assistance in the first 2 weeks, followed by spontaneous recovery. The majority of patients develop severe mental retardation and seizures. Some patients have agenesis of the corpus callosum or posterior fossa malformations. Most patients have restricted diffusion on MRI in the already myelinated long tracts at birth. Some patients with an attenuated form present with seizures, developmental delay, and mild chorea later in infancy or in childhood. All forms of the condition are autosomal recessive.

**Diagnosis**

Nonketotic hyperglycinemia should be suspected in any neonate or infant with seizures, particularly those with burst suppression pattern on EEG. Diagnosis is confirmed by demonstrating a large increase in glycine in non-bloody CSF, with an abnormally high ratio of CSF glycine to serum glycine. Molecular analysis is diagnostic in more than 90% of cases. Enzyme analysis on liver tissue can confirm the diagnosis. Prenatal diagnosis is possible by molecular analysis if both mutations are known or by enzyme assay on uncultured CVS.

**Treatment**

In patients with mild disease, treatment with sodium benzoate (to normalize serum glycine levels) and dextromethorphan or ketamine (to block N-methyl-d-aspartate type of glutamate receptors) controls seizures and improves outcome.
Treatment of severely affected patients is generally unsuccessful. High-dose benzoate therapy can aid in seizure control but does not prevent severe mental retardation.

Patient and parent support group website with useful information for families: http://www.nkh-network.org.

Organic acidemias are disorders of amino and fatty acid metabolism in which non-amino organic acids accumulate in serum and urine. These conditions are usually diagnosed by examining organic acids in urine, a complex procedure that requires considerable interpretive expertise and is usually performed only in specialized laboratories. Table 36–4 lists the clinical features of organic acidemias, together with the urine organic acid patterns typical of each. Additional details about some of the more important organic acidemias are provided in the sections that follow.

**PROPIONIC & METHYLMALONIC ACIDEMIA (KETOTIC HYPERGLYCINEMIAS)**

The oxidation of threonine, valine, methionine, and isoleucine results in propionyl-CoA, which propionyl-CoA carboxylase converts into L-methylmalonyl-CoA, which is metabolized through methylmalonyl-CoA mutase to succinyl-CoA. Gut bacteria and the breakdown of odd-chain-length fatty acids also substantially contribute to propionyl-CoA production. Propionic acidemia is due to a defect in the biotin-containing enzyme propionyl-CoA carboxylase, and methylmalonic aciduria is due to a defect in methylmalonyl-CoA mutase. In most cases the latter is due to a defect in the mutase apoenzyme, but in others it is due to a defect in the biosynthesis of its adenosyl-B$_{12}$ coenzyme.

In some of these defects, only the synthesis of adenosyl-B$_{12}$ is blocked; in others, the synthesis of methyl-B$_{12}$ is also blocked, and hence homocysteine is also elevated in blood in addition to methylmalonic acid.

Clinical symptoms in propionic and methylmalonic acidemia vary according to the location and severity of the enzyme block. Children with severe blocks present with acute, life-threatening metabolic acidosis, hyperammonemia, and bone marrow depression in early infancy or with metabolic acidosis, vomiting, and failure to thrive during the first few months of life. Most patients with severe disease have mild or moderate mental retardation. Late complications include pancreatitis, cardiomyopathy, and basal ganglia stroke, and in methylmalonic aciduria, interstitial nephritis.

All forms of propionic and methylmalonic acidemia are autosomal recessive traits (except for CblX [cobalamin X]) and can be diagnosed in utero.

**Diagnosis**

Laboratory findings consist of increases in urinary organic acids derived from propionyl-CoA or methylmalonic acid (see Table 36–4). Hyperglycinemia can be present. In some forms of abnormal vitamin B$_{12}$ metabolism, homocysteine can be elevated. Confirmation is by molecular analysis or by assays in fibroblasts.

**Treatment**

Patients with enzyme blocks in B$_{12}$ metabolism usually respond to massive doses of vitamin B$_{12}$ given intramuscularly. Vitamin B$_{12}$ non-responsive methylmalonic acidemia and propionic acidemia require amino acid restriction, strict prevention of catabolism, and carnitine supplementation to enhance propionylcarnitine excretion. Intermittent metronidazole can help reduce the propionate load from the gut. In the acute setting, hemodialysis or hemofiltration may be needed. Combined liver-renal transplantation is an option for patients with renal insufficiency, and liver transplantation has shown promise for patients with life-threatening cardiomyopathy.

ISOVALERIC ACIDEMIA

Isovaleric acidemia, caused by deficiency of isovaleryl-CoA dehydrogenase in the leucine oxidative pathway, was the first organic acidemia to be described in humans. Patients with this disorder usually present with poor feeding, metabolic acidosis, seizures, and an odor of sweaty feet during the first few days of life, with coma and death occurring if the condition is not recognized and treated. Other patients have a more chronic course, with episodes of vomiting and lethargy, hair loss, and pancreatitis precipitated by intercurrent infections or increased protein intake. The condition is autosomal recessive and can be diagnosed in utero.

**Diagnosis**

Isovalerylglycine is consistently detected in the urine by organic acid chromatography.

**Treatment**

Providing a low-protein diet or a diet low in leucine is effective. Conjugation with either glycine or carnitine helps in maintaining metabolic stability by removing toxic isovaleryl-CoA. Outcome is usually good.

GLUTARIC ACIDEMIA TYPE I

Isolated 3-methylcrotonyl-CoA carboxylase deficiency is frequently recognized on newborn screening using acylcarnitine analysis. It is usually a benign condition that only rarely causes symptoms of acidosis and neurologic depression. All carboxylases require biotin as a cofactor. Holocarboxylase synthetase and biotinidase are two enzymes of biotin metabolism. Holocarboxylase synthetase covalently binds biotin to the apocarboxylases for pyruvate, 3-methylcrotonyl-CoA, and propionyl-CoA; biotinidase releases biotin from these proteins and from proteins in the diet. Recessively inherited deficiency of either enzyme causes deficiency of all three carboxylases (ie, multiple carboxylase deficiency). Patients with holocarboxylase synthetase deficiency usually present as neonates with hypotonia, skin problems, and massive acidosis. Those with biotinidase deficiency present later with a syndrome of ataxia, seizures, seborrhea, and alopecia. Untreated patients can develop mental retardation, hearing loss, and optic nerve atrophy. Newborn screening is justified because the neurologic sequelae of the disorder in many patients are preventable if treated early.

**Diagnosis**

This diagnosis should be considered in patients with typical symptoms or in those with primary lactic acidosis. Urine organic acids are usually but not always abnormal (see Table 36–4). Diagnosis is made by enzyme assay of carboxylase activities in fibroblasts or leucocytes. Biotinidase can be assayed in serum, and holocarboxylase synthetase in leukocytes or fibroblasts.

**Treatment**

Oral administration of biotin in large doses often reverses the organic aciduria within days and the clinical symptoms within days to weeks. Hearing loss can occur in patients with biotinidase deficiency despite treatment.
Glutaric acidemia type I is due to deficiency of glutaryl-CoA dehydrogenase. Patients have frontotemporal atrophy with enlarged sylvian fissures and macrocephaly. Sudden or chronic neuronal degeneration in the caudate and putamen causes an extrapyramidal movement disorder in childhood with dystonia and athetosis. Children with glutaric acidemia type I may present with retinal hemorrhages and intracranial bleeding, and may thus be falsely considered victims of child abuse. Severely debilitated children often die in the first decade, but several reported patients have had only mild neurologic abnormalities. Most patients develop symptoms in the first 6 years of life. The condition is autosomal recessive and prenatal diagnosis is possible.

### Diagnosis
Glutaric acidemia type I should be suspected in patients with acute or progressive dystonia in the first 6 years of life. Magnetic resonance imaging of the brain is highly suggestive. The diagnosis is supported by finding glutaric, 3-hydroxyglutaric acid, and glutarylcarmitine in urine or serum or by finding two mutations in the GCDH gene. Demonstration of deficiency of glutaryl-CoA dehydrogenase in fibroblasts can further confirm the diagnosis. Prenatal diagnosis is by mutation analysis, enzyme assay, or quantitative metabolite analysis in amniotic fluid.

### Treatment
Strict catabolism prevention during any intercurrent illness is very important. Supplementation with large amounts of carnitine and provision of a lysine and tryptophan restricted diet may prevent degeneration of the basal ganglia, warranting newborn screening. Early diagnosis via newborn screening does not prevent neurologic disease in all patients, but it clearly reduces the risk. Neurologic symptoms, once present, do not resolve. Symptomatic treatment of severe dystonia is important for affected patients.

Deficiencies of very-long-chain and medium-chain acyl-CoA dehydrogenase (VLCAD, MCAD) and long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD), three enzymes of fatty acid β-oxidation, usually cause Reye-like episodes of hypoketotic hypoglycemia, mild hyperammonemia, hepatomegaly, and encephalopathy. Sudden death in infancy is a less common presentation. The long-chain defects, which also include carnitine palmitoyltransferase deficiency I and II and carnitine-acylcarnitine translocase deficiency, often also cause skeletal myopathy with hypotonia and episodic rhabdomyolysis. They also cause cardiomyopathy and ventricular arrhythmias. LCHAD deficiency may produce progressive liver cirrhosis, peripheral neuropathy, and retinitis pigmentosa. Mothers of affected infants can have acute fatty liver of pregnancy or HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets). Mild carnitine palmitoyltransferase I deficiency may cause renal tubular acidosis and hypertriglyceridemia. MCAD deficiency is common, occurring in perhaps 1:9000 live births. Reye-like episodes may be fatal or cause residual neurologic damage. Episodes tend to become less frequent and severe with time. After the diagnosis is made and treatment instituted, morbidity decreases and mortality is avoided in MCAD deficiency.

Short-chain acyl-CoA dehydrogenase (SCAD) deficiency is characterized by the presence of ethylmalonic acid in the urine, and although some patients have symptoms similar to those in MCAD deficiency, many are asymptomatic. Glutaric acidemia type II results from defects in the transfer of electrons from fatty acid oxidation and some amino acid oxidation into the respiratory chain. Some patients with glutaric acidemia type II have a clinical presentation resembling MCAD deficiency. Patients with a severe neonatal presentation also have renal cystic disease and dysmorphic features. The least affected patients can present with late-onset myopathy and be riboflavin responsive. Some develop cardiomyopathy or leukodystrophy. Deficiency of the ketogenic enzyme 3-hydroxyacylglycine oxidase presents with hypoketotic hypoglycemia. These conditions are autosomal recessive.
Diagnosis

The hypoglycemic presentation of Reye-like episodes is associated with a lack of an appropriate ketone response to fasting. Urine organic acid analysis in patients with MCAD deficiency reveals dicarboxylic acids and increased hexanoylglycine, suberylglycine, and phenylpropionylglycine. The finding of normal urine organic acids does not exclude these conditions, because the excretion of these acids is intermittent. Urine and blood findings in glutaric acidemia type II and SCAD deficiency are often diagnostic. The analysis of acylcarnitine esters is a first-line diagnostic test used in neonatal screening because it reveals diagnostic metabolites regardless of clinical status. MCAD deficiency is characterized by elevated octanoylcarnitine. A typical pattern can be recognized in deficiencies of VLCAD, LCHAD, carnitine-acylcarnitine translocase, and severe carnitine palmitoyltransferase. Further confirmation can be obtained from analysis of fatty acid oxidation in fibroblasts. Molecular sequencing is available for each defect with MCAD and LCHAD deficiencies, each having a common mutation. Assays for each enzyme can be done on fibroblasts in specialized laboratories.

Treatment

Management involves prevention of hypoglycemia by avoiding prolonged fasting (> 8–12 hours). This includes providing carbohydrate snacks before bedtime and vigorous treatment of fasting associated with intercurrent infections. Because fatty acid oxidation can be compromised by associated carnitine deficiency, young patients with MCAD deficiency usually receive oral carnitine. Restriction of dietary long-chain fats is not necessary in MCAD deficiency but is required for severe VLCAD and LCHAD deficiencies. Medium-chain triglycerides are contraindicated in MCAD deficiency but are an essential energy source for patients with severe VLCAD and LCHAD deficiencies or carnitine-acylcarnitine translocase deficiency. Riboflavin may be beneficial in some patients with glutaric acidemia type II. Outcome in MCAD deficiency is excellent but is more guarded in patients with the other disorders.

CARNITINE

Carnitine is an essential nutrient found in highest concentration in red meat. Its primary function is to transport long-chain fatty acids into mitochondria for oxidation. Primary defects of carnitine transport may manifest as Reye syndrome, cardiomyopathy, or skeletal myopathy with hypotonia. These disorders are rare compared with secondary carnitine deficiency, which may be due to diet (vegan diet, intravenous alimentation, or ketogenic diet), renal losses, drug therapy (especially valproic acid), and other metabolic disorders (especially disorders of fatty acid oxidation and organic acidemias). The prognosis depends on the cause of the carnitine abnormality. Primary carnitine deficiency is one of the most treatable causes of dilated cardiomyopathy in children.

Free and esterified carnitine can be measured in blood. Muscle carnitine may be low despite normal blood levels, particularly in respiratory chain disorders. If carnitine insufficiency is suspected, the patient should be evaluated to rule out disorders that might cause secondary carnitine deficiency.
Oral or intravenous L-carnitine is used in carnitine deficiency or insufficiency in doses of 25–100 mg/kg/d or higher. Treatment is aimed at maintaining normal carnitine levels. Carnitine supplementation in patients with some disorders of fatty acid oxidation and organic acidosis may also augment excretion of accumulated metabolites, although supplementation may not prevent metabolic crises in such patients.

### Treatment

Hyperhydration and alkalinization are essential to prevent kidney stones and urate nephropathy. Allopurinol and probenecid may be given to reduce hyperuricemia and prevent gout but do not affect the neurologic status. Physical restraints are often more effective than neurologic medications for automutilation. No effective treatment exists for adenylosuccinate lyase deficiency.

---

### LYSOSOMAL DISEASES

Lysosomes are cellular organelles in which complex macromolecules are degraded by specific acid hydrolases. Deficiency of a lysosomal enzyme causes its substrate to accumulate in the lysosomes, resulting in a characteristic clinical picture. These storage disorders are classified as mucopolysaccharidoses, lipidoses, or mucolipidoses, depending on the nature of the stored material. Two additional disorders, cystinosis and Salla disease, are caused by defects in lysosomal proteins that normally transport material from the lysosome to the cytoplasm. Table 36–5 lists clinical and laboratory features of these conditions. Most are inherited as autosomal recessive traits, and all can be diagnosed in utero.

### Diagnosis

The diagnosis of mucopolysaccharidosis is suggested by certain clinical and radiologic findings (dysostosis multiplex, which includes enlarged sella turcica, scaphocephaly, broad ribs, hook shaped vertebrae [L1 and L2 most affected], and prominent pointing of the metacarpals and broad phalanges). Urine screening tests can detect increased mucopolysaccharides and further identify which specific mucopolysaccharides are present. Diagnosis must be confirmed by enzyme assays of leukocytes or cultured fibroblasts. Analysis of urinary oligosaccharides indicates a specific disorder prior to enzymatic testing. Lipidoses present with visceral symptoms or neurodegeneration. The pattern of the leukodystrophy associated with many lipidoses can indicate a specific condition. Diagnosis is made by appropriate enzyme assays of peripheral leukocytes or cultured skin fibroblasts. Molecular analysis is also available for most conditions.

**CNS**, central nervous system; **ERT**, enzyme-replacement therapy; **HSCT**, hematopoietic stem cell transplantation; **RE**, reticuloendothelial; **SIT**, substrate inhibition therapy.

*a*May be useful in selected patients.

### Treatment

Most conditions cannot be treated effectively, but new avenues have given hope in many conditions. Hematopoietic stem cell transplantation can greatly improve the course of some lysosomal diseases and is first-line treatment in some, such as infantile Hurler syndrome. Several disorders are treated with infusions of recombinant modified enzyme. Treatment of Gaucher disease is very effective, and long-term data suggest excellent outcome. Similar treatments have been developed for Fabry disease, several mucopolysaccharidoses, and Pompe disease. Substantial improvements in these conditions have been reported but with limitations. New avenues for treatment through substrate inhibition and chaperone therapy are being developed. Treatment of cystinosis with cysteamine results in depletion of stored cystine and prevention of complications including renal disease.

---

**References**

Peroxisomal diseases are intracellular organelles that contain a large number of enzymes, many of which are oxidases linked to catalase. The enzyme systems in peroxisomes include β-oxidation of very-long-chain fatty acids, phytanic acid, and bile acids and the biosynthesis of plasmalogens. In addition, peroxisomes contain oxidases for D- and L-amino acids, pipecolic acid, and the biosynthesis of plasmalogens. In peroxisomal diseases, only a single enzyme is deficient. Zellweger (cerebrohepatorenal) syndrome, the best known among these, is caused by severe defects in organelle assembly. Patients present in infancy with seizures, hypotonia, characteristic facies with a large forehead and fontanel, and cholestatic hepatitis. At autopsy renal cysts and absent peroxisomes are seen. Patients with a similar but milder biochemical and clinical phenotype have neonatal adrenoleukodystrophy or neonatal Refsum disease. They often have detectable peroxisomes.

In other peroxisomal diseases, only a single enzyme is deficient. Primary hyperoxaluria (alanine-glyoxylate aminotransferase deficiency) causes renal stones and nephropathy. Mutations in the X-linked very-long-chain fatty acid transporter gene, ABCD1, cause either a rapid leukodystrophy with loss of function (adrenoleukodystrophy), slow progressive spasticity and neuropathy (adrenomyeloneuropathy), or adrenal insufficiency. Defective phytanic acid oxidation in adult Refsum disease causes ataxia, leukodystrophy, cardiomyopathy, neuropathy, and retinal dystrophy. Other isolated enzyme deficiencies can mimic Zellweger syndrome.

Abnormalities of plasmalogen synthesis are clinically associated with rhizomelic chondrodysplasia punctata. Except for adrenoleukodystrophy, all peroxisomal diseases are autosomal recessive and can be diagnosed in utero.

### Diagnosis

The best screening test for Zellweger syndrome and other biogenesis disorders is determination of very-long-chain fatty acids in serum or plasma. Urine bile acids are abnormal in other peroxisomal disorders. Phytanic acid and plasmalogens can also be measured. Together, these studies identify most peroxisomal diseases. Fibroblast enzyme assays followed by molecular analysis are needed for confirmation, especially when the parents plan further pregnancies.

### Treatment

Bone marrow transplantation may be an effective treatment at the early stages of adrenoleukodystrophy, and close monitoring of affected males is necessary. Adrenal insufficiency requires hydrocortisone substitution. Lorenzo’s oil, a mixture of glyceryl-trierucate and glyceryl-trioleate that suppresses endogenous very-long-chain fatty acid synthesis, in combination with a very-low-fat diet and essential fatty acid supplementation, is ineffective in patients with established symptoms but is under evaluation for prevention of neurologic symptoms in presymptomatic males with adrenoleukodystrophy. Dietary treatment is used and effective for adult Refsum disease. Liver transplantation protects the kidneys in severe primary hyperoxaluria.

Ebberink MS et al: Genetic classification and mutational spectrum of more than 600 patients with a Zellweger syndrome spectrum disorder. Hum Mutat 2011;32:59 [PMID: 21031596].

of disorders that result from defects in the synthesis of glycans or in the attachment of glycans to other compounds. N-linked, O-linked, and combined N- and O-linked glycosylation defects have been described. The most common N-linked defect is phosphomannomutase 2 deficiency or congenital disorders of glycosylation type Ia (CDG-Ia). Children with type Ia disease usually present with prenatal growth disturbance, often with abnormal fat distribution, cerebellar hypoplasia, typical facial dysmorphic features, and mental retardation. The typical course includes chronic liver disease, peripheral neuropathy, endocrinopathies, retinopathy, and in some patients, acute life-threatening events. Patients with type Ib disease have a variable combination of liver fibrosis, protein-losing enteropathy, and hypoglycemia. More than a dozen other forms are characterized by additional key symptoms, including coloboma, cutis laxa, severe epilepsy, ichthyosis, immunoglobulin deficiency, and Dandy-Walker malformation. Biochemical differences and variations in clinical course (eg, the absence of peripheral neuropathy) characterize the other types. Pathophysiology probably relates to defects of those biochemical pathways that require glycosylated proteins. Recently, O-linked glycosylation defects have been found to underlie more classically described genetic syndromes such as multiple exostoses syndrome, Walker-Warburg syndrome, muscle-eye-brain disease, and a number of α-dystroglycanopathies. The syndromes appear to be inherited in an autosomal recessive manner with the exception of multiple exostoses syndrome which is autosomal dominant. The frequency of N-linked glycosylation defects is estimated to be as high as 1:20,000 in northern Europe.

**Diagnosis**

Diagnosis is supported by finding altered levels of glycosylated enzymes or other proteins such as transferrin, thyroxine-binding globulin, lysosomal enzymes, and clotting factors (IX, XI, antithrombin III, and proteins C and S). However, these levels may be normal in carbohydrate-deficient glycoprotein syndromes or abnormal in other conditions. Diagnosis is confirmed by finding typical patterns of abnormal glycosylation of selected proteins. Most diagnostic laboratories examine serum transferrin to screen for N-linked defects and apoC1 for O-linked defects. Confirmatory diagnosis is by assaying enzyme activity, analysis of lipid-linked oligosaccharides in fibroblasts, and mutation analysis.

**Treatment**

Treatment is supportive, including monitoring and providing early treatment for expected clinical features. Mannose treatment is curative for patients with type Ib deficiency only.

**SMITH-LEMLI-OPITZ SYNDROME & DISORDERS OF CHOLESTEROL SYNTHESIS**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Elevated 7- and 8-dehydrocholesterol in serum and other tissue is diagnostic in Smith-Lemli-Opitz (SLO) syndrome which presents with developmental delay and malformations.
- Chondrodysplasia punctata, skin defects, and neurological symptoms can indicate other cholesterol synthetic defects.

Several defects of cholesterol synthesis are associated with malformations and neurodevelopmental disability. SLO syndrome is an autosomal recessive disorder caused by a deficiency of the enzyme 7-dehydrocholesterol Δ7-reductase. It is characterized by microcephaly, poor growth, mental retardation, typical dysmorphic features of face and extremities (particularly two- to three-toe syndactyly), and often malformations of the heart and genitourinary system. It is further described in Chapter 37. Other cholesterol synthetic defects are seen in Conradi Hünnermann syndrome, which includes chondrodysplasia punctata and atrophic skin. Cholestanolosis (cerebrotendinous xanthomatosis) manifests with progressive ataxia and cataracts.

**Diagnosis**

In SLO, elevated 7- and 8-dehydrocholesterol in serum or other tissues, including amniotic fluid, is diagnostic. Serum cholesterol levels may be low or in the normal range.
Enzymes of cholesterol synthesis may be assayed in cultured fibroblasts or amniocytes, and mutation analysis is possible.

**Treatment**

Although postnatal treatment does not resolve prenatal injury, supplementation with cholesterol in SLO improves growth and behavior. The role of supplemental bile acids is controversial. Simvastatin reduces 7- and 8-dehydrocholesterol and increases cholesterol levels by induction of its synthetic enzymes, but its effect on clinical symptoms is limited.

Pyridoxine-dependent epilepsy manifests as a severe seizure disorder in the neonatal or early infantile period that responds to high doses of pyridoxine. The disorder is caused by deficient activity of the enzyme α-amino adipic semialdehyde dehydrogenase resulting from mutations in the antiquitin (ALDH7A1) gene. Pyridoxal-phosphate–responsive encephalopathy manifests as a severe seizure disorder in infancy that responds to pyridoxal-phosphate. This disorder is caused by mutations in the PNPO gene encoding pyridox(am)ine oxidase, which is necessary for activation of pyridoxine.

**Diagnosis**

Although some disorders can be diagnosed by examining serum amino acids or urine organic acids (eg, 4-hydroxybutyric aciduria), in most cases, diagnosis requires analysis of CSF. Spinal fluid samples for neurotransmitter analysis require special collection and handling, as the neurotransmitter levels are graduated along the axis of the CNS and are highly unstable once the sample is collected. A phenylalanine loading test can be diagnostic for mild defects in GTP-cyclohydrolase deficiency, in which neurotransmitter analysis may be insufficiently sensitive. Analysis of CSF shows elevated threonine and decreased pyridoxal-phosphate in pyridoxal-phosphate–responsive disease, and decreased serine and glycine in serine biosynthetic defects. Urine α-amino adipic acid or piperidine-6-carboxylate can be used to identify infants with seizures that may be pyridoxine dependent.

**Treatment**

Biosynthesis defects of dopamine and serotonin are usually treated with a combination of levodopa, 5-hydroxytryptophan, and carbidopa. Pyridoxine-dependent epilepsy is treated with pyridoxine in high doses and can benefit from a lysine-restricted diet, whereas pyridoxal-phosphate–responsive encephalopathy requires pyridoxal-phosphate. For some conditions, such as pyridoxine-responsive seizures, pyridoxal-phosphate–responsive encephalopathy, or dopa-responsive dystonia, response to treatment can be dramatic. For others, response to therapy is less satisfactory in part because of poor penetration of the blood-brain barrier. Supplementation with serine and glycine can substantially improve outcome in serine deficiency.
Creatine and creatine phosphate are essential for storage and transmission of phosphate-bound energy in muscle and brain. They spontaneously convert to creatinine. Three disorders of creatine synthesis are now known: arginine:glycine amidinotransferase (AGAT) deficiency, guanidinoacetate methyltransferase (GAMT) deficiency, and creatine transporter (CrT1) deficiency. GAMT and AGAT deficiencies are autosomal recessive disorders, whereas CrT1 deficiency is X-linked. All patients demonstrate developmental delay, mental retardation, autistic behavior, seizures, and severe expressive language disturbance. Patients may also show developmental regression and brain atrophy. Patients with GAMT deficiency have more severe seizures and an extrapyramidal movement disorder. The seizure disorder is milder in CrT1-deficient patients. Some female heterozygotes of CrT1 deficiency may also show developmental delay or learning disabilities.

**Diagnosis**

The common feature of all creatine synthesis defects is a severe depletion of creatine and creatine phosphate in the brain demonstrable by reduction to absence of signal on magnetic resonance spectroscopy. In GAMT deficiency, guanidinoacetate accumulates, whereas in AGAT deficiency, guanidinoacetate is decreased, particularly in urine. Guanidinoacetate seems to be responsible for the severe seizures and movement disorder found in GAMT deficiency. Blood, urine, and CSF creatine levels are decreased in GAMT deficiency but normal in AGAT deficiency. Urine excretion of creatine is elevated in CrT1 deficiency. Enzyme and molecular analyses are available for diagnostic confirmation.

**Treatment**

Treatment with oral creatine supplementation is in part successful in GAMT and AGAT deficiencies. It is not beneficial in CrT1 deficiency. Treatment by combined arginine restriction and ornithine substitution in GAMT deficiency can decrease guanidinoacetate concentrations and improve the clinical course.

**Quality Initiatives in the Field of Metabolic Disease**

Expanded newborn screening has had a large impact on the field of metabolic disorders. As desired, patients are being diagnosed earlier, and for some patients, this dramatically reduces the disease burden. Expanded newborn screening, however, has also uncovered problems or revealed unexpected consequences that need to be addressed. For example, the clinical spectrum of many disorders is being expanded to include mildly affected or asymptomatic patients. This raises care questions particularly in regard to the need for aggressive management in the more mildly affected patients or if therapy is needed all for some patients. It is unclear whether some patients diagnosed who are on the milder end of a disease spectrum would have ever become symptomatic or presented to care. Consequently, for some disorders, disease incidence appears to be changing. In addition, newborn screening for several conditions has brought to light our ability to detect maternal disease. Disorders such as maternal B₉ deficiency and maternal carnitine uptake deficiency pose management as well as risk questions for this largely asymptomatic population. Conditions felt by most to be benign are also being diagnosed as a consequence of expanded newborn screening. Further, owing to limitations in diagnostic testing, patients...
who may be carriers for a condition are now being treated, as the carrier status cannot be entirely confirmed nor the condition entirely excluded. This is particularly true for disorders such as glutaric acidemia, type I, and VLCAD deficiency. This not only adds to parental anxiety, but treatment of an unaffected child may entail risk to the child or to family dynamics.

Improvement in diagnostic testing, especially the sensitivity of molecular and enzymatic testing, may help improve the diagnostic conundrum. National initiatives are underway in an attempt to clarify other issues. Initiated under regional programs and now under the guidance of the American College of Medical Genetics and the Newborn Screening Translational Research Network (NBSTRN), uniform clinical data sets for disorders diagnosed via newborn screening have been developed. The hope is also for a national database for data collection integrating clinical care, public health, and state laboratories. The overall goal is to track the long-term outcome of individuals diagnosed with inborn errors of metabolism, to define best practice guidelines, and to determine the benefit of newborn screening. In addition, the NBSTRN seeks to stimulate research in newborn screening, advocate pilot screening programs, and establish a national, virtual dried blood spot repository for research. This national initiative is inclusive of all disorders for which newborn screening occurs, not just inborn errors of metabolism.

Another national focus is the expansion of newborn screening to other genetic disorders. Currently, some states are beginning to implement newborn screening for severe combined immunodeficiency (SCID) and for lysosomal storage disorders such as Pompe disease, Fabry disease, Gaucher disease, and Krabbe disease. A pilot study is also underway for screening for spinal muscular atrophy, and screening for disorders such as Fragile X syndrome and Prader Willi syndrome is being considered. As technology for early detection and treatment strategies advance, more disorders will likely be considered candidates for newborn screening. Additionally, some conditions being considered for screening affect an individual after the newborn period. Second-tier, childhood screening for such late-onset disorders may be a consideration in the future. Careful consideration will need to be given regarding the risks and benefits to screening for such conditions. The U.S. Secretary for Health and Human Services’ Advisory Committee on Heritable Disorders in Newborns and Children has established a rigorous process for disease review before recommending a disorder be considered for screening.

Genetics is an exciting and rapidly evolving field that has significant relevance to the understanding of human embryology, physiology, and disease processes. Tremendous advances in molecular biology and biochemistry are allowing more comprehensive understanding of mechanisms inherent in genetic disorders as well as improved diagnostic tests and management options. Many of the newer technologies and terms may be unfamiliar to the clinician in practice. Thus, the topics in the first part of the chapter serve as an introduction and review of the basic principles of genetics, including basic knowledge of cytogenetics and molecular biology. The second part discusses principles of inherited human disorders, encompassing different genetic mechanisms as well as how to obtain a genetic history and pedigree. Topics in the third part of the chapter focus on applied clinical genetics which include dysmorphology, teratology, and perinatology. Common clinical disorders with descriptions of the diseases and discussion of their pathogenesis, diagnosis, and management are also included.

**FOUNDATIONS OF GENETIC DIAGNOSIS**

**CYTOGENETICS**

Cytogenetics is the study of genetics at the chromosome level. Chromosomal anomalies occur in 0.4% of all live births and are a common cause of intellectual disabilities (formerly called mental retardation) and congenital anomalies. The prevalence of chromosomal anomalies is much higher among spontaneous abortions and stillbirths.

**Chromosomes**

Human chromosomes consist of DNA (the blueprint of genetic material), specific proteins forming the backbone of the chromosome (called histones), and other chromatin structural and interactive proteins. Chromosomes contain most of the genetic information necessary for growth and differentiation. The nuclei of all normal human cells, with the exception of gametes, contain 46 chromosomes, consisting of 23 pairs (Figure 37–1). Of these, 22 pairs are called autosomes. They are numbered according to their size; chromosome 1 is the largest and chromosome 22 the smallest. In addition, there are two sex chromosomes: two X chromosomes in females and one X and one Y chromosome in males. The two members of a chromosome pair are called homologous chromosomes. One homolog of each chromosome pair is maternal in origin (from the egg); the second is paternal (from the sperm). The egg and sperm each contain 23 chromosomes (haploid cells). During formation of the zygote, they fuse into a cell with 46 chromosomes (diploid cell).

**Cell Division**

Cells undergo cycles of growth and division that are controlled according to their needs and functions.

*Mitosis* is a kind of cell division, occurring in stages, during which DNA replication takes place and two daughter cells, genetically identical to the original parent cells, are formed. This cell division is typical for all somatic cells (cells other than the sperm or egg, which are called germine cells). There are four phases of mitosis: interphase, prophase, metaphase, and anaphase. In interphase, chromosomes are long, thin, and nonvisible. At this time, the genetic material is replicated. In prophase, the chromosomes are more condensed. During metaphase (the phase following DNA replication but preceding cell division), individual chromosomes can be visualized. Each arm consists of two identical parts, called chromatids. Chromatids of the same chromosome are called sister chromatids. In anaphase, the genetic material is separated into two cells.
Meiosis is a kind of cell division during which eggs and sperm are formed; it is a cell division limited to gametes. During meiosis, three unique processes take place:

1. Crossing over of genetic material between two homologous chromosomes (this recombination, or exchange of genetic material increases the viability of human beings).
2. Random assortment of maternally and paternally derived homologous chromosomes into the daughter cells.
3. Two cell divisions, the first of which is a reduction division—that is, separation between the homologous chromosomes. The second meiotic division is like mitosis, separating two sister chromatids into two daughter cells.

Chromosome Preparation & Analysis

Chromosome structure is visible only during mitosis, most often achieved in the laboratory by stimulating a blood lymphocyte culture with a mitogen for 3 days. Other tissues used for this purpose include skin, products of conception, cartilage, and bone marrow. Chorionic villi or amniocytes are used for prenatal diagnosis. Spontaneously dividing cells without a mitogen are present in bone marrow, and historically, bone marrow biopsy was done when immediate identification of a patient’s chromosome constitution was necessary for appropriate management (eg, to rule out trisomy 13 in a newborn with a complex congenital heart disease). However, this invasive test has been replaced by the availability of the FISH technique (see the following discussion).

Cells processed for routine chromosome analysis are stained on glass slides to yield a light-and-dark band pattern across the arms of the chromosomes (see Figure 37–1). This band pattern is characteristic and reproducible for each chromosome, allowing the chromosomes to be identified. Using different staining techniques, different banding patterns result: G, Q, and R banding. The most commonly used is G banding. The layout of chromosomes on a sheet of paper in a predetermined order is called a karyotype. High-resolution chromosome analysis is the study of more elongated chromosomes in prometaphase. Although the bands can be visualized in greater detail, subtle chromosomal rearrangements less than 5 million base pair (5 Mb) can still be missed.

Fluorescence in situ hybridization (FISH) is a powerful technique that labels a known chromosome sequence with DNA probes attached to fluorescent dyes, thus enabling visualization of specific regions of chromosomes by fluorescent microscopy. There are many different kinds of probes, including paint probes (a mixture of sequences throughout one chromosome), sequence-specific probes, centromere probes, and telomere probes. A cocktail of differently colored probes, one color for each chromosome, called multicolor FISH, or M-FISH, can detect complex rearrangements between chromosomes. FISH can detect submicroscopic structural rearrangements undetectable by classic cytogenetic techniques and can identify marker chromosomes. (For pictures of FISH studies, go to http://www.kumc.edu/gec/prof/cytogene.html.)

Interphase FISH allows noncultured cells (lymphocytes, amniocytes) to be rapidly screened for numerical abnormalities such as trisomy 13, 18, or 21, and sex chromosome anomalies. However, because of the possible background or contamination of the signal, the abnormality must be confirmed by conventional chromosome analysis in aneuploidy cases. Six hundred–cell FISH can also be used to ascertain mosaicism.
Chromosomal Microarray Analysis

Advances in computer technology and bioinformatics have led to the development of new genetic testing using comparative genomic hybridization with microarray technique. This technique allows detection of very small genetic imbalances anywhere in the genome. Its usefulness has been well documented in cancer research and more recently in assessing small chromosomal rearrangements. In particular, it has been used to detect interstitial and subtelomeric submicroscopic imbalances, to characterize their size at the molecular level, and to define the breakpoints of translocations. Clinically available arrays include (1) 0.5- to 1-Mb bacterial artificial chromosome arrays that can pick up rearrangements greater than 0.5 Mb, (2) oligonucleotide arrays using special probes that can pick up changes as small as 3 Kb, and (3) single nucleotide polymorphism (SNP) arrays, which are used more widely in research settings. Although this powerful new technology can identify extremely subtle DNA rearrangements and changes, many human polymorphisms, including small deletions and duplications, are not totally understood. Therefore, special caution and parental studies are often required in interpreting the results.

Chromosome Nomenclature

Visible under the microscope is a constriction site on the chromosome called the centromere, which separates the chromosome into two arms: p, for petite, refers to the short arm, and q, the letter following p, refers to the long arm. Each arm is further subdivided into numbered bands visible using different staining techniques. Centromeres are positioned at different sites on different chromosomes and are used to differentiate the chromosome structures seen during mitosis as metacentric (p arm and q arm of almost equal size), submetacentric (p arm shorter than q arm), and acrocentric (almost no p arm). The use of named chromosome arms and bands provides a universal method of chromosome description. Common symbols include del (deletion), dup (duplication), inv (inversion), ish (in situ hybridization), i (isochromosome), pat (paternal origin), mat (maternal origin), and r (ring chromosome). These terms are further defined in the section Chromosomal Abnormalities.

Chromosomal Abnormalities

There are two types of chromosomal anomalies: numerical and structural.

A. Abnormalities of Chromosomal Number

When a human cell has 23 chromosomes, such as human ova or sperm, it is in the haploid state (n). After conception, in cells other than the reproductive cells, 46 chromosomes are present in the diploid state (2n). Any number that is an exact multiple of the haploid number—for example, 46(2n), 69(3n), or 92(4n)—is referred to as euploid. Polyploid cells are those that contain any number other than the usual diploid number of chromosomes. Polyploid conceptions are usually not viable except in a “mosaic state,” with the presence of more than one cell line in the body (see later text for details).

Cells deviating from the multiple of the haploid number are called aneuploid, meaning not euploid, indicating an abnormal number of chromosomes. Trisomy, an example of aneuploidy, is the presence of three of a particular chromosome rather than two. It results from unequal division, called nondisjunction, of chromosomes into daughter cells. Trisomies are the most common numerical chromosomal anomalies found in humans (eg, trisomy 21 [Down syndrome], trisomy 18, and trisomy 13). Monosomies, the presence of only one member of a chromosome pair, may be complete or partial. Complete monosomies may result from nondisjunction or anaphase lag. All complete autosomal monosomies appear to be lethal early in development and only survive in mosaic forms. Sex chromosome monosomy, however, can be viable.

B. Abnormalities of Chromosomal Structure

Many different types of structural chromosomal anomalies exist. Figure 37–2 displays the formal nomenclature as well as the ideogram demonstrating chromosomal anomalies. In clinical context, the sign (+) or (−) preceding the chromosome number indicates increased or decreased number, respectively, of that particular whole chromosome in a cell. For example, 47, XY+21 designates a male with three copies of chromosome 21. The sign (+) or (−) after the chromosome number signifies extra material or missing material, respectively, on one of the arms of the chromosome. For example, 46, XX, 8q− denotes a deletion on the long arm of chromosome 8. Detailed nomenclature, such as 8q11, is required to further demonstrate a specific missing region so that genetic counseling can be provided.

1. Deletion (del) (see Figure 37–2A)—This refers to an absence of normal chromosomal material. It may be terminal (at the end of a chromosome) or interstitial (within a chromosome). The missing part is described using the code “del,” followed by the number of the chromosome involved in parentheses, and a description of the missing region of that chromosome, also in parentheses, for example, 46, XX, del(1) (p36.3). This chromosome nomenclature describes the loss of genetic material from band 36.3 of the short arm of chromosome 1, which results in 1p36.3 deletion syndrome. Some more common deletions result in clinically recognizable conditions associated with intellectual
disabilities and characteristic facial features. (See descriptions of common genetic disorders caused by chromosomal deletions later in the chapter.)

2. Duplication (dup) (see Figure 37–2B)—An extra copy of a chromosomal segment can be tandem (genetic material present in the original direction) or inverted (genetic material present in the opposite direction). A well-described duplication of chromosome 22q11 causes Cat eye syndrome, resulting in iris coloboma and anal or ear anomalies.

3. Inversion (inv) (see Figure 37–2C)—In this aberation, a rearranged section of a chromosome is inverted. It can be paracentric (not involving the centromere) or pericentric (involving the centromere).

4. Ring chromosome (r) (see Figure 37–2D)—Deletion of the normal telomeres (and possibly other subtelomeric sequences) leads to subsequent fusion of both ends to form a circular chromosome. Ring chromosomal anomalies often cause growth retardation and intellectual disability.

5. Translocation (trans) (see Figure 37–2E)—This interchromosomal rearrangement of genetic material may be balanced (the cell has a normal content of genetic material arranged in a structurally abnormal way) or unbalanced.
(the cell has gained or lost genetic material as a result of chromosomal interchange). Balanced translocations may further be described as reciprocal, the exchange of genetic material between two nonhomologous chromosomes, or Robertsonian, the fusion of two acrocentric chromosomes.

6. Insertion (ins) (see Figure 37–2F)—Breakage within a chromosome at two points and incorporation of another piece of chromosomal material is called insertion. This requires three breakpoints and may occur between two chromosomes or within the same chromosome. The clinical presentation or phenotype depends on the origin of the inserted materials.

C. Sex Chromosomal Anomalies
Abnormalities involving sex chromosomes, including aneuploidy and mosaicism, are relatively common in the general population. The most common sex chromosome anomalies include 45,X (Turner syndrome), 47,XXX,47,XXY (Klinefelter syndrome), 47,XYY, and different mosaic states. (See later text for clinical discussion.)

D. Mosaicism
Mosaicism is the presence of two or more different chromosome constitutions in different cells of the same individual. For example, a patient may have some cells with 47 chromosomes and others with 46 chromosomes (46,XX/47,XX,+21 indicates mosaicism for trisomy 21; similarly, 45,X/46,XX/47,XXX indicates mosaicism for a monosomy and a trisomy X). Mosaicism should be suspected if clinical symptoms are milder than expected in a nonmosaic patient with the same chromosomal abnormality, or if the patient’s skin shows unusual pigmentation. The prognosis is frequently better for a patient with mosaicism than for one with a corresponding chromosomal abnormality without mosaicism. In general, the smaller the proportion of the abnormal cell line, the better the prognosis. In the same patient, however, the proportion of normal and abnormal cells in various tissues, such as skin, brain, internal organs, and peripheral blood, may be significantly different. Therefore, the prognosis for a patient with chromosomal mosaicism can seldom be assessed reliably based on the karyotype in peripheral blood alone.

E. Uniparental Disomy
Under normal circumstances, one member of each homologous pair of chromosomes is of maternal origin from the egg and the other is of paternal origin from the sperm (Figure 37–3A). In uniparental disomy (UPD), both copies of a particular chromosome pair originate from the same parent. If UPD is caused by an error in the first meiotic division, both homologous chromosomes of that parent will be present in the gamete—a phenomenon called heterodisomy (Figure 37–3B). If the disomy is caused by an error in the second meiotic division, two copies of the same chromosome will be present through the mechanism of rescue, duplication, and complementation (Figure 37–3C through 37–3E)—a phenomenon called isodisomy. Isodisomy may also occur as a postfertilization error (Figure 37–3F).

A chromosomal analysis would not reveal an abnormality, but DNA analysis would reveal that the child inherited two copies of DNA of a particular chromosome from one parent without the contribution from the other parent. Possible mechanisms for the adverse effects of UPD include homozygosity for deleterious recessive genes and the consequences of imprinting (see discussion in the Imprinting section, later). It is suspected that UPD of some chromosomes is lethal.

UPD has been documented for certain human chromosomes, including chromosomes 7, 11, 15, and X, and has been found in patients with Prader-Willi, Angelman, and Beckwith-Wiedemann syndromes (BWS). In addition, cystic fibrosis with only one carrier parent (caused by maternal isodisomy) has been reported. UPD may cause severe prenatal and postnatal growth retardation.

F. Contiguous Gene Syndromes
Contiguous gene syndromes result when a deletion causes the loss of genes adjacent to each other on a chromosome. Although many genes may be missing, the deletion may still be too small to be detected by routine karyotype. Therefore, contiguous gene syndromes are sometimes called “microdeletion syndromes.” The genes involved in these syndromes are related only through their linear placement on the same chromosome segments and may not influence each other’s functions directly. Table 37–1 lists examples of some currently known contiguous gene syndromes and their associated chromosomal abnormalities. These deletions may be familial (passed on by a parent) or may occur de novo. The deletions may be diagnosed by high-resolution chromosome analysis in some affected individuals, or may be submicroscopic and detectable only with FISH or DNA analysis.

G. Chromosome Fragility
Disorders of DNA repair are associated with chromosomal breakage and death of somatic cells. Most are autosomal recessive. Phenotypes vary considerably (Table 37–2). As a group these disorders typically affect growth and CNS development. They show increased toxicity to mutagen exposures in vitro. Photosensitivity, increased cancer risks, and premature aging are prevalent. Treatment is largely supportive and focuses on surveillance for complications but in at least one disorder, Fanconi anemia, bone marrow transplant can be beneficial. See www.genereviews.org for excellent reviews of these disorders.

H. Chromosomal Abnormalities in Cancer
Numerical and structural chromosomal abnormalities are often identified in hematopoietic and solid-tumor neoplasms in individuals with otherwise normal chromosomes. These cytogenetic abnormalities have been categorized as primary and secondary. In primary abnormalities, their
presence is necessary for initiation of the cancer; an example is 13q− in retinoblastoma. Secondary abnormalities appear de novo in somatic cells only after the cancer has developed, for example, Philadelphia chromosome, t(9;22)(q34;q11), in acute and chronic myeloid leukemia. Primary and secondary chromosomal abnormalities are specific for particular neoplasms and can be used for diagnosis or prognosis. For example, the presence of the Philadelphia chromosome is a good prognostic sign in chronic myelogenous leukemia and indicates a poor prognosis in acute lymphoblastic leukemia. The sites of chromosome breaks coincide with the known loci of oncogenes and antioncogenes.

MOLECULAR GENETICS

Advances in molecular biology have revolutionized human genetics, as they allow for the localization, isolation, and characterization of genes that encode protein sequences. As the Human Genome Project has moved into the postcloning era, the function of gene products and their interaction with one another has become the main theme of molecular genetics. Molecular genetics can help explain the complex underlying biology involved in many human diseases.

Molecular diagnosis can be achieved using the following technology: Southern blot analysis is the molecular genetic technique used to look for changes in genomic DNA. A similar technique, called Northern blot analysis, is used to look for RNA abnormalities. Western blot analysis is used to look for protein changes. The polymerase chain reaction (PCR) replicates fragments of DNA between predetermined primers so that sufficient DNA is obtained for characterization or sequencing in the space of a few hours. Quantitative fluorescent PCR combines PCR amplification with fluorescent DNA probes to provide real-time replication and rapid determination of gene copy number and dosage effects. DNA sequencing is the process of determining the nucleotide order of a given DNA fragment. A new generation of sequencing technologies has provided unprecedented opportunities for high-throughput functional genomic research. To date, these technologies have been applied in a variety of contexts, including whole-genome sequencing which can be performed in 1 week; however, the interpretation of the sequencing requires more bioinformatics information. National Institutes of Health (NIH) predicted the eventual cost for whole genome can be reduced to $1000.

Molecular Biology in Clinical Genetics & Genetic Diagnosis

Genetic diagnosis can be performed by direct detection of a mutant gene or by indirect methods. Direct detection is possible only when the gene causing the disease and the nature of the mutation are known. The advantage of a diagnostic study using the direct detection of a mutant gene is that it requires the affected individual only and need not involve the testing of other family members. The methods of direct DNA diagnosis include restriction analysis, direct sequencing with assistance of PCR, heteroduplex assay, and protein truncation assay. The molecular mechanisms causing human diseases include point mutations, deletions, insertions, and the unstable expansion of trinucleotide repeats, which leads to genetic anticipation. Some disorders that may be diagnosed via direct DNA mutational analysis include Duchenne muscular dystrophy, hemophilia, cystic fibrosis, and Fragile X syndrome.

Indirect detection of abnormal genes is used when the gene is known but there is extensive heterogeneity of the molecular defect between families, or when the gene responsible for a disease is unknown but its chromosome location is known. One form of indirect analysis is the linkage method.
Linkage traces the inheritance of the abnormal gene between members of a kindred. This method requires that the affected individual be studied, as well as parents and other relatives, both affected and unaffected. Linkage analysis is performed by using markers such as a restriction fragment length polymorphisms. Microsatellite polymorphisms are being used in sibling research studies to identify the multiple genes that contribute to polygenic traits such as diabetes and obesity. They are also used increasingly to identify gene changes in tumors.

Neurofibromatosis is an example of a disorder in which both the direct and indirect assay may be used. An estimated 90%–95% of patients with neurofibromatosis type 1 have a mutation or deletion that can be identified using a direct assay of the neurofibromin gene (NFI). The other cases must rely on indirect methods such as linkage analysis for prenatal diagnosis.

Molecular Biology in Prevention & Treatment of Human Diseases

Molecular diagnosis can prevent genetic disease by detection of mutation and permitting prenatal diagnosis. As diseases often present in spectrums and clinical features among disorders can overlap, molecular testing is useful to confirm a diagnosis. Family studies can also clarify the mode of inheritance, thus allowing more accurate determination of recurrence risks and appropriate options. For example, differentiation of gonadal mosaicism from decreased penetrance of a dominant gene has important implications for genetic counseling. In the past, the diagnosis of a genetic disease characterized by late onset of symptoms (eg, Huntington disease) could not be made prior to the appearance of clinical symptoms. In some inborn errors of metabolism, diagnostic tests (eg, measurement of enzyme activities) could be conducted only on inaccessible tissues. Gene identification (mutation analysis) techniques can enormously enhance the ability to diagnose both symptomatic and presymptomatic individuals, heterozygous carriers of gene mutations, and affected fetuses. However, presymptomatic DNA testing is associated with psychological, ethical, and legal implications and therefore should be used only with informed consent. Formal genetic counseling is indicated to best interpret the results of molecular testing.

A normal gene introduced into an individual affected with a serious inherited disorder during embryonic life (germline therapy) in principle has the potential to be transmitted to future generations, whereas its introduction into somatic cells (somatic therapy) affects only the recipient. Experimental gene therapy by bone marrow transplantation is being tried for adenosine deaminase deficiency. Recombinant enzyme replacement has been successfully applied in treating the nonneurologic form of Gaucher disease, Fabry disease, Pompe disease, mucopolysaccharidosis types I and II, and some types of lysosomal storage disease.

Proteomics is the large-scale study of proteins, particularly their structures and functions. The term “proteomics” was first coined in 1997 as an analogy to genomics, the study of the genes. “Proteome” means a blend of “protein” and “genome.” Understanding the proteome, the structure and function of each protein and the complexities of protein-protein interactions will be critical for developing effective diagnostic techniques and disease treatments. One of the most promising roles of proteomics has been the identification of potential new drugs for the treatment of disease. This relies on genome and proteome information to identify proteins associated with a disease, which computer software can then use as targets for new drugs. For example, in Alzheimer disease, elevations in beta secretase create amyloid/beta-protein, which causes plaque to build up in the patient’s brain, which is thought to play a role in dementia. Targeting this enzyme decreases the amyloid/beta-protein and so slows the progression of the disease.

Pharmacogenomics is a new field offering enormous promise for predicting drug response in patients. For example, by DNA analysis of two specific genes, CYP2C9 and VKORC1, it is now possible to predict response to warfarin anticoagulation therapy and to individualize the dose, saving the patient multiple blood tests and dosage adjustments. It is also possible to predict which patients would be at risk for hearing loss after receiving aminoglycoside treatment, based on mutations in the mitochondrial 12S rRNA gene.

Personalized medicine is an advancing field of medicine that offers increased precision and effectiveness than traditional medicine. A patient’s genomic information offers insight into the individual aspects of one’s medical management. The goal is to optimize care and overall outcomes, one example being the aforementioned area of pharmacogenomics and potential therapeutic responses.

Genetic testing allows practitioners to test patients for a wide variety of genetic conditions. Advances in this area of medicine have included the advent of parents requesting testing for adult onset disease, carrier status, and disease susceptibility in their children. There are significant ethical and legal issues surrounding this topic. The American College of Medical Genetics and Genomics and American Society of Human Genetics formed a consensus statement on the topic that educates families and healthcare providers on the potential negative impacts of such testing. In the face of whole exome or genome sequencing, single-gene analysis, and microarray analysis, carrier status for conditions may be revealed and this requires detailed genetic counseling. The decision-making capacity of the minor should also be taken into account where applicable.

or expression in different tissues or organ systems. In

Pleiotropy refers to the phenomenon whereby a single mutant allele can have widespread effects or expression in different tissues or organ systems. In other words, an allele may produce more than one effect on the phenotype. For example, Marfan syndrome has manifestations in different organ systems (skeletal, cardiac, ophthalmologic, etc) due to a single mutation within the fibrillin gene.

5. Penetrance—Penetrance refers to the proportion of individuals with a particular genotype that express the same phenotype. Penetrance is a proportion that ranges between 0 and 1 (or 0 and 100%). When 100% of mutant individuals express the phenotype, penetrance is complete. If some mutant individuals do not express the phenotype, penetrance is said to be incomplete, or reduced. Dominant conditions with incomplete penetrance, therefore, are characterized by “skipped” generations with unaffected, obligate gene carriers.

6. Expressivity—Expressivity refers to the variability in degree of phenotypic expression (severity) seen in different individuals with the same mutant genotype. Expressivity may be extremely variable or fairly consistent, both within and between families. Intrafamilial variability of expression may be due to factors such as epistasis, environment, genetic anticipation, presence of phenocopies, mosaicism, and chance (stochastic factors). Interfamilial variability of expression may be due to the previously mentioned factors, but may also be due to allelic or locus genetic heterogeneity.

7. Genetic heterogeneity—Several different genetic mutations may produce phenotypes that are identical or similar enough to have been traditionally considered as one diagnosis. “Anemia” or “mental retardation” are examples of this. There are two types of genetic heterogeneity, locus heterogeneity and allelic heterogeneity.

A. Locus heterogeneity—Locus heterogeneity describes a phenotype caused by mutations at more than one genetic locus; that is, mutations at different loci cause the same phenotype or a group of phenotypes that appear similar enough to have been previously classified as a single disease, clinical “entity,” or diagnostic spectrum. An example would be Sanfilippo syndrome (mucopolysaccharidosis types IIIA, B, C, and D), in which the same phenotype is produced by four different enzyme deficiencies.

B. Allelic heterogeneity—A phenotype causing different mutations at a single-gene locus. As an example, cystic fibrosis may be caused by many different genetic changes, such as homozygosity for the common ΔF508 mutation, or ΔF508 and an R117H mutation. The latter example represents compound heterozygosity.

8. Phenotypic heterogeneity or “clinical heterogeneity”—This term describes the situation in which more than one phenotype is caused by different allelic mutations at a single locus. For example, different mutations in the FGFR2 gene can cause different craniosynostosis disorders, including Crouzon
syndrome, Jackson-Weiss syndrome, Pfeiffer syndrome, and Apert syndrome. These syndromes are clinically distinguishable and are due to the presence of a variety of genetic mutations within single genes.

9. Homozygous—A cell or organism that has identical alleles at a particular locus is said to be homozygous. For example, a cystic fibrosis patient with a ΔF508 mutation on both alleles would be called homozygous for that mutation.

10. Heterozygous—A cell or organism that has nonidentical alleles at a genetic locus is said to be heterozygous. In autosomal dominant conditions, a mutation of only one copy of the gene pair is all that is necessary to result in a disease state. However, an individual who is heterozygous for a recessive disorder will not manifest symptoms (see the next section).

11. Karyotype—A profile of an organism’s chromosomes that is sorted according to size, shape, and number. It is available for analysis in a number of sample types (white blood cells, fibroblasts, etc). It is able to detect structural rearrangements such as inversions, positional insertions, and translocations. Imbalances below 5 million base pairs are difficult to detect.

12. Chromosomal microarray—Method of cytogenetic analysis via several platforms: BAC, oligonucleotide, and SNP. Patient DNA is hybridized with control DNA and each is labeled with a different fluorescent dye. Data is plotted on a log2 scale, as in the case of oligonucleotide arrays, and reviewed for numerical imbalances. Microarray is limited in the detection of balanced rearrangements and the structural nature of an imbalance.

13. Next-generation sequence analysis—Genetic analysis via breakage of the genome into fragments, attaching those segments of DNA to special adapters, or passage through specialized channels where the sequence is determined. Millions of segments are analyzed simultaneously, lending the term “high throughput” to this approach. Regions are repeatedly analyzed and compared with a reference human genome.

14. Whole exome sequencing—Determination of the sequence of an individual’s exome, the coding sequence of the human genome. Exome represents only about 1% of the genome.

15. Whole genome sequencing—Determination of the sequence of the entire human genome.

Hereditary Patterns

A. Autosomal Dominant Inheritance

Autosomal dominant inheritance has the following characteristics:

1. If a parent is affected, the risk for each offspring of inheriting the abnormal dominant gene is 50%, or 1:2. This is true whether the gene is penetrant or not in the parent.

2. Affected individuals in the same family may experience variable expressivity.

3. Nonpenetration is common, and the penetrance rate varies for each dominantly inherited condition.

4. Both males and females can pass on the abnormal gene to children of either sex, although the manifestations may vary according to sex. For example, pattern baldness is a dominant trait but affects only males. In this case, the trait is said to be sex-limited.

5. Dominant inheritance is typically said to be vertical, that is, the condition passes from one generation to the next in a vertical fashion (Figure 37–4).

6. In some cases, the patient appears to be the first affected individual in the family. This spontaneous appearance is often caused by a new mutation. The mutation rate increases with advancing paternal age (particularly after age 40 years).

7. Explanations for a negative family history include:
   A. Nonpaternity.
   B. Decreased penetrance or mild manifestations in one of the parents.
   C. Germline mosaicism (ie, mosaicism in the germ cell line of either parent). Germline mosaicism may

\[ \text{Figure 37–4.} \text{ Autosomal dominant inheritance.} \]

Variable expressivity in Neurofibromatosis type 1.
mimic autosomal recessive inheritance, because it leads to situations in which two children of completely normal parents are affected with a genetic disorder. Recurrence risks are in the range of 1%–7%.

D. The abnormality present in the patient may be a phenocopy, or it may be a similar but genetically different abnormality with a different mode of inheritance.

8. As a general rule, dominant traits are more often related to structural abnormalities of a protein.

9. If an abnormality represents a new mutation of a dominant trait, the parents of the affected individual run a low risk during subsequent pregnancies. The risk for an affected sibling is still slightly increased over the general population, because of the possibility of germ-line mosaicism.

10. Prevention options available for future pregnancies include prenatal diagnosis, artificial insemination, and germ cell donation.

**B. Autosomal Recessive Inheritance**

Autosomal recessive inheritance also has some distinctive characteristics:

1. The recurrence risk for parents of an affected child is 25%, or 1:4 for each pregnancy. The gene carrier frequency in the general population can be used to assess the risk of having an affected child with a new partner, for unaffected siblings, and for the affected individuals themselves.

2. There is less variability among affected persons. Parents are carriers and are clinically normal. (There are, however, exceptions to this rule. For example, carriers of sickle cell trait may become symptomatic if they become hypoxic.)

3. Males and females are affected equally.

4. Inheritance is horizontal; siblings may be affected (Figure 37–5).

5. The family history is usually negative, with the exception of siblings. However, in common conditions such as cystic fibrosis, a second- or third-degree relative may be affected.

6. Recessive conditions are frequently associated with enzyme defects.

7. In rare instances, a child with a recessive disorder and a normal karyotype may have inherited both copies of the abnormal gene from one parent and none from the other. This UPD was first described in a girl with cystic fibrosis and growth retardation.

8. Options available for future pregnancies include prenatal diagnosis, adoption, artificial insemination, and egg or sperm donation.

**C. X-Linked Inheritance**

When a gene for a specific disorder is on the X chromosome, the condition is said to be X-linked, or sex-linked. Females may be either homozygous or heterozygous, because they have two X chromosomes. Males, by contrast, have only one X, and a male is said to be hemizygous for any gene on his X chromosome. The severity of any disorder is greater in males than in females (within a specific family). According to the Lyon hypothesis, because one of the two X chromosomes in each cell is inactivated, and this inactivation is random, the clinical picture in females depends on the percentage of mutant versus normal alleles inactivated. The X chromosome is not inactivated until about 14 days of gestation, and parts of the short arm remain active throughout life.

1. **X-linked recessive inheritance**—The following features are characteristic of X-linked recessive inheritance:

   1. Males are affected, and heterozygous females are either normal or have mild manifestations.

   2. Inheritance is diagonal through the maternal side of the family (Figure 37–6A).
3. A female carrier has a 50% chance that each daughter will be a carrier and a 50% chance that each son will be affected.

4. All of the daughters of an affected male are carriers, and none of his sons are affected.

5. The mutation rate is high in some X-linked disorders, particularly when the affected male dies or is so incapacitated by the disorder that reproduction is unlikely. In such instances, the mutation is thought to occur as a new mutation in the affected male, and in the mother, each one-third of the time and to be present in earlier generations one-third of the time. For this reason, genetic counseling may be difficult in families with an isolated case.

6. On rare occasions, a female may be fully affected. Several possible mechanisms may account for a fully affected female: (a) unfavorable lyonization; (b) 45,X karyotype; (c) homozygosity for the abnormal gene; (d) an X-autosome translocation, or other structural abnormality of one X chromosome, in which the X chromosome of normal structure is preferentially inactivated; (e) UPD; and (f) nonrandom inactivation, which may be controlled by an autosomal gene.

Figure 37-6. A: X-linked recessive inheritance. B: X-linked dominant inheritance.
2. X-linked dominant inheritance—The X-linked dominant inheritance pattern is much less common than the X-linked recessive type. Examples include incontinentia pigmenti and hypophosphatemic or vitamin D–resistant rickets. The following features are characteristic of X-linked dominant inheritance:

1. The heterozygous female is symptomatic, and the disease is twice as common in females because they have two X chromosomes that can have the mutation.
2. Clinical manifestations are more variable in females than in males.
3. The risk for the offspring of heterozygous females to be affected is 50% regardless of sex.
4. All of the daughters but none of the sons of affected males will have the disorder (Figure 37–6B).
5. Although a homozygous female is possible (particularly in an inbred population), she would be severely involved. All of her children would also be affected but more mildly.
6. Some disorders (eg, incontinentia pigmenti) are lethal in males (and in homozygous females). Affected women have twice as many daughters as sons and an increased incidence of miscarriages, because affected males will be spontaneously aborted. A 47,XXY karyotype has allowed affected males to survive.

D. Y-Linked Inheritance

In Y-linked inheritance, also known as “holandric” inheritance, a disorder is caused by genes located on the Y chromosome. These conditions are relatively rare with only about 40 entries listed in McKusick’s catalog. Male-to-male transmission is seen in this category, with all sons of affected males being affected and no daughters or females being affected.

Multifactorial Inheritance

Many common attributes, such as height, are familial, and are the result of the actions of multiple rather than single genes. Inheritance of these traits is described as polygenic or multifactorial. The latter term recognizes that environmental factors such as diet also contribute to these traits. Geneticists are now finding that multiple genes are often expressed in hierarchies, in which the action of a small number of genes, two or three, explains much of the variation observed within affected populations.

Studies of twins have proven useful in determining the relative importance of genetic versus environmental factors in the expression of polygenic traits. If genetic factors are of little or no importance, then the concordance between monozygotic and dizygotic twins should be the same. (Dizygotic twins are no more genetically similar to each other than to other siblings.) If an abnormality is completely genetic, the concordance between identical twins should be 100%. In polygenic conditions, the concordance rate for identical twins is usually higher than that seen in dizygotic twins but is still not 100%, indicating that both genetic and environmental factors are playing a role.

Many disorders and congenital abnormalities that are clearly familial but do not segregate as mendelian traits (eg, autosomal dominant, recessive) show polygenic inheritance. For the most part, these conditions become manifest when thresholds of additive gene actions or contributing environmental factors are exceeded. Many common disorders ranging from hypertension, stroke, and thrombophlebitis to behavioral traits such as alcoholism demonstrate multifactorial (polygenic) inheritance. Some common birth defects, including isolated congenital heart disease, cleft lip and palate, and neural tube defects, also demonstrate polygenic inheritance. Neural tube defects provide a good model illustrating how identification of both environmental and genetic contributions to multifactorial traits can lead to preventive measures.

Polygenic or multifactorial inheritance has several distinctive characteristics:

1. The risk for relatives of affected persons is increased. The risk is higher for first-degree relatives (those who have 50% of their genes in common) and lower for more distant relations, although the risk for the latter is higher than for the general population (Table 37–3).
2. The recurrence risk varies with the number of affected family members. For example, after one child is born with a neural tube defect, the recurrence risk is 2%–3%. If a second affected child is born, the risk for any future child increases to 10%–12%. This is in contrast to single-gene disorders, in which the risk is the same no matter how many family members are affected.
3. The risk is higher if the defect is more severe. In Hirschsprung disease, another polygenic condition, the longer the aganglionic segment, the higher is the recurrence risk.
4. Sex ratios may not be equal. If a marked discrepancy exists, the recurrence risk is higher if a child of the less commonly affected sex has the disorder. This assumes that more genetic factors are required to raise the more resistant sex above the threshold. For example, pyloric stenosis is more common in males. If the first affected child is a female, the recurrence risk is higher than if the child is a male.
5. The risk for the offspring of an affected person is approximately the same as the risk for siblings, assuming that the spouse of the affected person has a negative family history. For many conditions, however, assortative mating, “like marrying like,” adds to risks in offspring.

**NONMENDELIAN INHERITANCE**

**Epigenetic Regulation**

Although development is regulated by genes, it is initiated and sustained by nongenetic processes. Epigenetic events are points of interaction between developmental programs and the physicochemical environments in differentiating cells. Genetic imprinting and DNA methylation are examples of epigenetic processes that affect development. Certain genes important in regulation of growth and differentiation are themselves regulated by chemical modification that occurs in specific patterns in gametes. For example, genes that are methylated are “turned off” and not transcribed. The pattern of which genes are methylated may be determined or affected by the sex of the parent of origin (see the next section). Expression of imprinted genes may sometimes be limited to specific organs (eg, the brain), and imprinting may be relaxed and methyl groups lost as development progresses. Disruption of imprinting is now recognized as contributing to birth defect syndromes (described in the next section). Certain techniques developed to assist infertile couples (advanced reproductive technology) may affect epigenetic processes and lead to genetic disorders in the offspring conceived via these methods.

**Imprinting**

Although the homologs of chromosome pairs may appear identical on routine karyotype analysis, it is now known that the parental origin of each homolog can affect which genes are actually transcribed and which are inactivated. The term imprinting refers to the process by which preferential transcription of certain genes takes place, depending on the parental origin, that is, which homolog (maternal or paternal) the gene is located on. Certain chromosomes, particularly chromosome X, and the autosomes 15, 11, and 7, have imprinted regions where some genes are only read from one homolog (ie, either the maternal or paternal allele) under normal circumstances, and the gene on the other homolog is normally inactivated. Errors in imprinting may arise because of uniparental disomy or UPD (in which a copy from one parent is missing), by a chromosomal deletion causing loss of the gene normally transcribed, or by mutations in the imprinting genes that normally code for transcription or inactivation of other genes downstream. A good example of how imprinting may affect human disease is Beckwith-Wiedemann syndrome, the gene for which is located on chromosome 11p15.

Genetic Anticipation

Geneticists coined the term “anticipation” to describe an unusual pattern of inheritance in which symptoms became manifest at earlier ages and with increasing severity as traits are passed to subsequent generations. Mapping of the genes responsible for these disorders led to the discovery that certain repeat sequences of DNA at disease loci were not stable when passed through meiosis. Repeated DNA sequences, in particular triplets (e.g., CGG and CAG), tended to increase their copy number. As these runs of triplets expanded, they eventually affected the expression of genes and produced symptoms. Curiously, all the disorders undergoing triplet repeat expansion detected thus far produce neurologic symptoms. Most are progressive. In general, the size of the triplet expansion is roughly correlated with the timing and severity of symptoms. The reasons for the meiotic instability of these sequences are not yet understood. The mechanisms appear to involve interactions between DNA structure (e.g., formation of hairpin loops) and replication enzymes (DNA polymerase complexes) during meiosis.

Triplet repeat instability can modify the inheritance of autosomal dominant, autosomal recessive, and X-linked traits. Autosomal dominant disorders include several spinal cerbellar atrophies, Huntington disease, and myotonic dystrophy. Unstable triplet repeat expansion contributes to at least one autosomal recessive disorder, Friedreich ataxia. The most common X-linked disorder demonstrating triplet repeat instability and expansion is Fragile X syndrome.

Mitochondrial Inheritance

Mitochondrial disorders can be caused by both nuclear and mitochondrial genes. The former would follow Mendelian inheritance, either AR, AD, or X-Linked, while the latter demonstrates mitochondrial inheritance. Mitochondrial DNA is double-stranded, circular, and smaller than nuclear DNA, and is found in the cytoplasm. It codes for enzymes involved in oxidative phosphorylation, which generates adenosine triphosphate. Since the 1990s, enormous advances in technology and improved clinical documentation have led to a better understanding of the interesting disorders caused by mutations in mitochondrial DNA (mtDNA).

Mitochondrial disorders can be associated with point mutations, deletions, or duplications in mtDNA. However, there is a threshold effect depending on the heteroplasmic (see next). Because of the difficulty in predicting mitochondrial DNA disorders and the variability of the clinical course, it is often difficult to calculate specific recurrence risks.

Mitochondrial disorders related to mtDNA have the following characteristics:

1. They show remarkable phenotypic variability.
2. They are maternally inherited, because only the egg has any cytoplasmic material, and during early embryo-genesis any sperm-born mitochondrial material will be eliminated.
3. In most mitochondrial disorders, cells are heteroplasmic (Figure 37–7). That is, all cells contain both normal and mutated or abnormal mtDNA. The proportion of normal to abnormal mtDNA in the mother’s egg seems to determine the severity of the offspring’s disease and the age at onset in most cases.
4. Those tissues with the highest adenosine triphosphate requirements—specifically, central nervous system (CNS) and skeletal muscle—seem to be most susceptible to mutations in mtDNA.
5. Somatic cells show an increase in mtDNA mutations and a decline in oxidative phosphorylation function with age. This explains the later onset of some of these disorders and may indeed be a clue to the whole aging process.

FAMILY HISTORY & PEDIGREE

Critical in the evaluation of a potential genetic condition is the construction of a family tree, also known as a pedigree. Underused by most medical personnel, the pedigree is a valuable record of genetic and medical information, which is
much more useful in visual form than in list form. Tips for pedigree preparation include the following:

- Start with the proband—the patient’s siblings and parents, and obtain a three-generational history at minimum, as possible.
- Always ask about consanguinity.
- Obtain data from both sides of the family.
- Ask about spontaneous abortions, stillbirths, infertility, children relinquished for adoption, and deceased individuals.

In the course of taking the family history, one may find information that is not relevant in elucidating the cause of the patients’ problem but may indicate a risk for other important health concerns. Conditions unrelated to the chief complaint should be directed for follow-up care. Examples of the latter scenario include: an overwhelming family history of early-onset breast and ovarian cancer, or multiple pregnancy.

DYSMORPHOLOGY & HUMAN EMBRYOLOGY

Birth defects are the leading cause of death in the first year of life. They are evident in 2%–3% of newborn infants and in up to 7% of adults. Many are now detected by ultrasound prior to birth. Clinical investigation of the causes and consequences of birth defects is called dysmorphology.

MECHANISMS

Developmental Biology

Cell proliferation and programmed cell death (apoptosis) both contribute to embryonic structural formation. The genes that control these processes continue to be further characterized. Products of other genes establish regulatory pathways in which positive and negative signaling loops initiate and maintain cell differentiation with precise timing. Cell biology provides techniques that allow experimental access to developmental pathways. Embryology has become more experimental than descriptive and practitioners can expect systems biology to soon begin to inform them about the origins of specific birth defects. Further understanding of these mechanisms will open the door to interventions that may well prevent birth defects or treat them prenatally.

An example of the evolution of the aforementioned process is the ground breaking fetal surgery for neural tube defects.

Cellular Interactions

The picture emerging from experimental studies of morphogenesis is one of a hierarchy of gene expression during development. Morphogenesis begins with expression of genes encoding transcription factors. These proteins bind to DNA in undifferentiated embryonic cells and recruit them into developmental fields, groups of cells primed to respond to specific signals later in development. The recruitment also establishes spatial relationships and orients cells with respect to their neighbors. As fields differentiate into identifiable tissues (eg, ectoderm, mesoderm, and endoderm), cellular proliferation, migration, and further differentiation are mediated through genes encoding cell signaling proteins.

Signaling proteins include growth factors and their receptors, cellular adhesion molecules, and extracellular matrix proteins that both provide structure and position signals to developing tissues.

Environmental Factors

The effects of exogenous agents during development are also mediated through genetically regulated pathways. At the cellular level, xenobiotics (compounds foreign to nature) cause birth defects either because they disrupt cell signaling and thereby misdirect morphogenesis, or because they are cytotoxic and lead to cell death in excess of the usual developmental program.

In general, drug receptors expressed in embryos and fetuses are the same molecules that mediate pharmacologic effects in adults. However, effector systems may be different, reflecting incomplete morphogenesis and differences between fetal and postnatal physiology. These circumstances allow prediction of dose-response relationships during development on the one hand, but call for caution about predicting effects on the other.

Xenobiotics must traverse the placenta to affect embryonic and fetal tissues. The human placenta is a relatively good barrier against microorganisms, but it is ineffective at excluding drugs and many chemicals. The physicochemical properties (eg, molecular size, solubility, and charge) that allow foreign chemicals to be absorbed into the maternal circulation also allow them to cross the placenta. The placenta can metabolize some xenobiotics but it is most active against steroid hormones and low-level environmental contaminants than drugs.

The timing of xenobiotic exposures is an important determinant of their effects. Morphogenic processes express the so-called critical periods, during which developing organs they produce are particularly susceptible to maldevelopment. Critical periods of susceptibility are not all confined to early gestation. The developing brain is susceptible to toxicity throughout pregnancy.

Over-the-counter, prescribed, and abused drugs that are pharmacologically active in mothers will be active across
the placenta. Exposure to agents achieving cytotoxic levels in adults is likely to be teratogenic (ie, cause birth defects). Abused substances such as alcohol that are toxic to adults are predictably toxic to embryos and fetuses. Drugs generally safe in adults will be generally safe for fetuses. An exception is ibuprofen with its prostaglandin blocking properties that can affect fetal circulation, which is prostaglandin dependent. It is important to keep in mind that embryonic and fetal physiology may differ from that of an adult with respect to drug action.

Effects of toxic environmental contaminants on the embryo and fetus are dose-dependent. Thus, the level of exposure to a toxin frequently becomes the primary determinant of its risk. Exposures producing symptoms in mothers can be assumed to be potentially toxic to the fetus.

Transplacental pharmacologic effects can be therapeutic. The potential for embryonic and fetal drug therapies during pregnancy is increasing. Folic acid supplementation can lower risks for birth defects such as spina bifida, and maternally administered corticosteroids can induce fetal synthesis and secretion of pulmonary surfactants prior to delivery.

**Mechanical Factors**

Much of embryonic development and all of fetal growth occurs normally within the low pressure and space provided by amniotic fluid. Loss or inadequate production of amniotic fluid can have disastrous effects, as can disruption of placental membranes. Disruption of placental membranes in early gestation leads to major structural distortion and most often lethal. Later, deformation or even amputation of fetal extremities (amniotic band sequence) can occur.

Movement is also important for morphogenesis. Fetal movement is necessary for normal development of joints and is the principal determinant of folds and creases present at birth in the face, hands, feet, and other areas of the body. Clubfoot is an etiologically heterogeneous condition in which the foot is malpositioned at birth. It more often results from mechanical constraint secondary to intrauterine crowding, weak fetal muscles, or abnormal neurologic function than from primary skeletal maldevelopment.

Lung and kidney development are particularly sensitive to mechanical forces. Constriction of the chest through maldevelopment of the ribs, lack of surrounding amniotic fluid, or lack of movement (fetal breathing) leads to varying degrees of pulmonary hypoplasia in which lungs are smaller than normal and develop fewer alveoli. The presentation at birth is respiratory distress and may be lethal.

Cystic renal dysplasia is frequently associated with obstruction ureters or bladder outflow. As pressure within obstructed renal collecting systems increases, it distorts cell interactions and alters histogenesis. Developing kidneys exposed to increased internal pressures for long periods eventually become nonfunctional.

**CLINICAL DYSMORPHOLOGY**

An important task for the clinician presented with an infant with a birth defect is to determine whether the problem is isolated or part of a larger embryopathy (syndromic).

**Terminology**

Classification of dysmorphic features strives to reflect mechanisms of maldevelopment. However, much of the terminology that describes abnormal development in humans remains historical and documents recognition of patterns prior to understanding of their biology. For example, birth defects are referred to as **malformations** when they result from altered genetic or developmental processes. When physical forces interrupt or distort morphogenesis, their effects are termed **disruptions** and **deformations**, respectively. The term **dysplasia** is used to denote abnormal histogenesis. Malformations occurring together more frequently than would be expected by chance alone may be classified as belonging to **associations**. Those in which the order of maldevelopment is understood may be referred to as **sequences**.

For example, Robin sequence (or Pierre Robin anomaly) is used to describe cleft palate that has occurred because poor growth of the jaw (retrognathia) has displaced the tongue and prevented posterior closure of the palate. **Syndromes** are simply recurrent patterns of maldevelopment, in many with a known genetic cause.

**Evaluation of the Dysmorphic Infant**

As with any medical problem the history and physical examinations provide most of the clues to diagnosis. Special aspects of these procedures are outlined in the following sections. The extent of an infant’s abnormalities may not be immediately apparent, and parents who feel grief and guilt are often desperate for information.

**A. History**

Pregnancy histories nearly always contain important clues to the diagnosis. Parental recall after delivery of an abnormal infant is better than recall after a normal birth. An obstetric wheel can help document gestational age and events of the first trimester: the last menstrual period, the onset of symptoms of pregnancy, the date of diagnosis of the pregnancy, the date of the first prenatal visit, and the physician’s impressions of fetal growth at that time. Family histories should always be reviewed. Environmental histories should include descriptions of parental habits and work settings in addition to medications and use of drugs, tobacco, and alcohol.

**B. Physical Examination**

Meticulous physical examination is crucial for accurate diagnosis in dysmorphic infants and children. In addition to
the routine procedures described in Chapter 2, special attention should be paid to the neonate’s physical measurements (Figure 37–8). Photographs are helpful and should include a consistent method of measurement for reference.

C. Imaging and Laboratory Studies

Radiologic investigation is fundamental in the assessment and management of dysmorphic patients. A series of 9 plain radiographs, called a skeletal survey, is useful in the evaluation of patients with suspected skeletal dysplasia. Magnetic resonance imaging (MRI), with or without angiogram, venogram, or spectroscopy, contributes to diagnostic evaluation. Computed tomography (CT) is useful for bony structure assessment, but less so for deep tissue evaluation in comparison to MRI. Ultrasonography also has case-dependent utility for noninvasive imaging. Consultation with a radiologist is encouraged if there is any question about which imaging modality would serve the patient best.

Traditional cytogenetic analysis provides specific diagnoses in approximately 5% of dysmorphic infants who survive the neonatal period. Chromosomal abnormalities are recognized in 10%–15% of infants who die. With the availability of chromosomal microarray at least 10%–15% additional subtle chromosomal anomalies have been identified. Of note, many copy number variations (CNVs) exist in different individuals; therefore, interpretation is sometimes difficult and may require parental samples for clarification. Common disorders such as trisomies 21, 13, and 18 can be determined rapidly through use of FISH, but this technique should be accompanied by a complete karyotype. As a rule, a normal karyotype does not rule out the presence of significant genetic disease. Any case requiring rapid diagnosis should be discussed with an experienced clinical geneticist.

D. Perinatal Autopsy

When a dysmorphic infant dies, postmortem examination can provide important diagnostic information. The pediatrician should discuss the case thoroughly with the pathologist, and photographs should be obtained. Radiologic imaging should be included whenever limb anomalies or disproportionate growth is present. Tissue, most often skin, can be submitted for cytogenetic analysis. Fibroblasts from cytogenetic analysis can routinely be frozen and preserved for future studies. The pediatrician and the pathologist should also consider whether samples of blood, urine, or other tissue should be obtained for biochemical analyses. Placental as well as fetal tissue can be used for viral culture.

TRISOMIES

1. Trisomy 21 (Down Syndrome)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Characteristic features include upslanting palpebral fissures, epicanthal folds, midface hypoplasia, and small, dysplastic pinnae.
- Generalized hypotonia.
- Cognitive disabilities (usually mild to moderate).
- Associated with congenital heart disease and gastrointestinal anomalies.

Down syndrome occurs in about 1:700 newborns. Cognitive disabilities in the mild/moderate range are characteristic of Down syndrome, as is generalized hypotonia. The affected newborn may have prolonged physiologic jaundice, polycythemia, and a transient leukemoid reaction. Feeding problems are common during infancy. Problems which may be seen during childhood include thyroid dysfunction, visual issues, hearing loss, obstructive sleep apnea, celiac disease, atlanto-occipital instability, and autism. Leukemia is 12–20 times more common in patients with Down syndrome.

Clinical Findings

The principal physical findings include a flattened occiput, characteristic facies (upslanting palpebral fissures, epicanthal folds, midface hypoplasia, and small, dysplastic pinnae), and minor limb abnormalities. About one-third to one-half of children with Down syndrome have congenital heart disease, most often endocardial cushion defects or other septal defects. Anomalies of the gastrointestinal tract, including esophageal and duodenal atresias, are seen in about 15% of cases.

2. Trisomy 18 Syndrome

The incidence of trisomy 18 syndrome is about 1:4000 live births, and the ratio of affected males to females is approximately 1:3. Trisomy 18 is characterized by prenatal and postnatal growth retardation, which is often severe, and hypertonicity.

\(^a\)Internipple distance should not exceed 25% of chest circumference.

### Figure 37–8
Neonatal measurements.
Complications are related to associated birth defects. Death is often caused by heart failure or pneumonia and usually occurs in infancy or early childhood, although a small percentage of patients reach adulthood. Surviving children show significant cognitive disabilities.

**Clinical Findings**

Infants with trisomy 18 are often small for gestational age and have dysmorphic features including a characteristic facies and extremities (overlapping fingers and rocker-bottom feet) and congenital heart disease (often ventricular septal defect or patent ductus arteriosus). To see clinical pictures of patients with trisomy 18, visit the following website: [http://medgen.genetics.utah.edu/photographs/pages/trisomy_18.htm](http://medgen.genetics.utah.edu/photographs/pages/trisomy_18.htm).

### 3. Trisomy 13 Syndrome

The incidence of trisomy 13 is about 1 per 12,000 live births, and 60% of affected individuals are female. Most infants with trisomy 13 have congenital anomalies that are incompatible with survival. Surviving children demonstrate failure to thrive, cognitive disabilities, apneic spells, seizures, and deafness. Death usually occurs in early infancy or by the second year of life, commonly as a result of heart failure or infection.

**Clinical Findings**

The symptoms and signs include characteristic features, often a normal birth weight, CNS malformations, eye malformations, cleft lip and palate, polydactyly or syndactyly, and congenital heart disease. The facies of an infant with trisomy 13 can be viewed at the following website: [www.trisomy.org](http://www.trisomy.org).

**Treatment of Trisomies**

#### A. Medical Therapy

Interventions for specific issues such as surgery or medications for heart problems, antibiotics for infections, serial thyroid function tests, infant stimulation programs, special education, and physical, occupational, and speech therapies are all indicated. The goal of treatment is to help affected children develop to their full potential. Parents’ participation in support groups such as the local chapter of the National Down Syndrome Congress should be encouraged. See the following website: [http://www.ndss.org/](http://www.ndss.org/).

There is no treatment other than general supportive care for trisomy 13 or 18. Rapid confirmation of suspected Trisomy 13 or 18 can be made by FISH. A support group for families of children with trisomies 13 and 18 who survive beyond infancy is called SOFT. See the following website: [http://www.trisomy.org/](http://www.trisomy.org/).

### 3. Trisomy 13 Syndrome

#### B. Genetic Counseling

Most parents of trisomic infants have normal karyotypes. The risk of having a child affected with a trisomy increases with maternal age. For example, age-specific risks are approximately 1 per 1500 for mothers aged 25 years; and 1 per 100 for mothers at age 40. The recurrence risk for trisomy in future pregnancies is equal to 1 per 100 plus the age-specific maternal risk.

If the child has a trisomy resulting from a translocation, and the parent has an abnormal karyotype, the risks are increased. When the mother is the carrier of a balanced Robertsonian translocation, there is a 10%–15% chance that the child will be affected and a 33% chance that the child will be a balanced translocation carrier. When the father is the carrier, there is a smaller than 0.5% chance of having another affected child. If the child has a 21/21 translocation and one parent has the translocation, the recurrence risk is 100%.

The mother’s age at the time of conception and the nature of the chromosomal abnormality are important in genetic counseling, which is indicated for parents of all children with chromosomal abnormalities. Prenatal diagnosis is available.

### SEX CHROMOSOME ABNORMALITIES

#### 1. Turner Syndrome (Monosomy X, Gonadal Dysgenesis)

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Webbed neck, triangular facies, short stature, wide-set nipples, amenorrhea, and absence of secondary sex characteristics.
- Associated with coarctation of the aorta and genitourinary malformations.
- IQ is usually normal but learning disabilities are common.
- Mosaic individuals may manifest only short stature and amenorrhea.

The incidence of Turner syndrome is 1 per 10,000 females. However, it is estimated that 95% of conceptuses with monosomy X are miscarried and only 5% are liveborn.

**Clinical Findings**

Newborns with Turner syndrome may have webbed neck, edema of the hands and feet, coarctation of the aorta, and a characteristic triangular facies. Later symptoms include
short stature, a shield chest with wide-set nipples, streak ovaries, amenorrhea, absence of secondary sex characteristics, and infertility. Some affected girls, particularly those with mosaicism, have only short stature and amenorrhea, without dysmorphic features.

Complications relate primarily to coarctation of the aorta, when present. Malformations of the urinary tract may be seen. Learning disabilities are common, secondary to difficulties in perceptual motor integration.

**Treatment**

In Turner syndrome the identification and treatment of perceptual difficulties before they become problematic is very important. Estrogen replacement therapy permits development of secondary sex characteristics and normal menstruation and prevents osteoporosis. Growth hormone therapy has been used to increase the height of affected girls. Females with 45,X or 45,X mosaicism have a low fertility rate, and those who become pregnant have a high risk of fetal wastage (spontaneous miscarriage, ~30%; stillbirth, 6%–10%). Furthermore, their liveborn offspring have an increased frequency of chromosomal abnormalities involving either sex chromosomes or autosomes and congenital malformations. Thus, prenatal ultrasonography and chromosome analysis are indicated for the offspring of females with sex chromosome abnormalities.

**2. Klinefelter Syndrome (XXY)**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Diagnosis is rarely made before puberty.
- Key findings include microorchidism; lack of libido; minimal facial hair; and tall, eunuchoid build.
- IQ can vary (normal to borderline with a small percentage showing cognitive disabilities).

The incidence of Klinefelter syndrome in the newborn population is roughly 1 per 1000, but it is about 1% among intellectual disabilities and about 3% among males seen at infertility clinics. The maternal age at birth is often advanced. Unlike Turner syndrome, Klinefelter syndrome is rarely the cause of spontaneous abortions. The diagnosis is seldom made before puberty except as a result of prenatal diagnosis, because prepubertal boys have a normal phenotype.

**Clinical Findings**

The characteristic findings after puberty include microorchidism associated with otherwise normal external genitalia, azoospermia, sterility, gynecomastia, normal to borderline IQ, diminished facial hair, lack of libido and potency, and a tall, eunuchoid build. In chromosome variants with three or four X chromosomes (XXXY and XXXXY), intellectual disabilities may be severe, and radioulnar synostosis may be present as well as anomalies of the external genitalia and cryptorchidism. In general, the physical and mental abnormalities associated with Klinefelter syndrome increase as the number of sex chromosomes increases.

**Treatment**

Males with Klinefelter syndrome require testosterone replacement therapy. The presence of the extra X chromosome may allow expression of what might normally be a lethal X-linked disorder to occur.

**3. XYY Syndrome**

Newborns with XYY syndrome in general are normal. Affected individuals may on occasion exhibit an abnormal behavior pattern from early childhood and may have mild intellectual disabilities. Fertility may be normal. Many males with an XYY karyotype are normal. There is no treatment.

**4. XXX Syndrome**

The incidence of females with an XXX karyotype is approximately 1 per 1000. Females with XXX are phenotypically normal. However, they tend to be taller than usual and to have lower IQs than their normal siblings. Learning and behavioral issues are relatively common. This is in contrast to individuals with XXXX, a much rarer condition causing more severe developmental issues, and a dysmorphic phenotype reminiscent of Down syndrome.
abnormality exists in mosaic form. Two examples of this include trisomy 8 and Cat eye syndrome, caused by extra genetic material, which is derived from a portion of chromosome 22.

CHROMOSOME DELETION DISORDERS

Three common chromosomal deletion disorders that were previously detected on routine karyotype analysis, and confirmed via FISH assay, but are now detected with microarray, are 1p36− syndrome, Wolf-Hirschhorn syndrome (4p−), and cri du chat syndrome (5p−). Microdeletion or contiguous gene syndrome are referring to those small deletion not readily picked up by karyotype but detected by microarray or FISH.

1. Deletion 1p36 Syndrome

Microcephaly and a large anterior fontanelle are characteristic features of 1p36− syndrome. Cardiac defects are common, and dilated cardiomyopathy may present in infancy. Intellectual disability, hypotonia, hearing loss, and seizures are usually seen.

2. Wolf-Hirschhorn Syndrome

Also known as 4p− (deletion of 4p16), this syndrome is characterized by microcephaly and unusual development of the nose and orbits that produces an appearance suggesting an ancient Greek warrior’s helmet. Other anomalies commonly seen include cleft lip and palate and cardiac and renal defects. Seizure disorders are common, and the majority of patients have severe intellectual disability.

3. Cri du Chat Syndrome

Also known as 5p− (deletion of terminal chromosome 5p), this disorder is characterized by unique facial features, growth retardation, and microcephaly. Patients have an unusual catlike cry. Most patients have major organ anomalies and significant intellectual disability.

CONTIGUOUS GENE DISORDERS

Three common contiguous gene disorders which are usually suspected on the basis of an abnormal phenotype and then confirmed microarray are Williams syndrome, Smith-Magenis syndrome, and Velocardiofacial syndrome. The meiotic mechanisms responsible for interstitial chromosomal deletions causing these disorders also result in duplications. We now understand that interstitial chromosomal duplications in the following regions also produce abnormal phenotypes:

1. Williams Syndrome

Williams syndrome is a contiguous gene disorder that deletes the gene for elastin and other neighboring genes at 7q11.2. It is characterized by short stature; congenital heart disease (supravalvular aortic stenosis); coarse, elfin-like facies with prominent lips; hypercalcaemia or hypercalciuria in infancy; developmental delay; and neonatal irritability evolving into an overly friendly personality. Calcium restriction may be necessary in early childhood to prevent nephrocalcinosis. The hypercalcaemia often resolves during the first year of life. The natural history includes progression of cardiac disease and predisposition to hypertension and spinal osteoarthritis in adults. Most patients have mild to moderate intellectual deficits.

Duplication of chromosome 7q11.2 results in a syndrome that includes speech delay, and features of autistic spectrum disorders. Physical features are less consistent than in Williams syndrome.

2. Smith-Magenis Syndrome

This syndrome is associated with microdeletion of 17p11 and is characterized by prominent forehead, deep-set eyes, cupid-shaped upper lip, self-mutilating behavior, sleep disturbance, and intellectual disabilities. Some patients also have seizure disorders, hearing loss, thyroid disease, and immunological and lipid abnormalities.

Duplication of 17p11 produces Potocki-Lupski syndrome that is characterized by growth failure, variable levels of cognitive deficiencies, autistic features, and, occasionally, structural abnormalities of the heart.

3. Velocardiofacial Syndrome

(Deletion 22q11 Syndrome)

Also known as DiGeorge syndrome, this condition was originally described in newborns presenting with cyanotic congenital heart disease, usually involving great vessel abnormalities; thymic hypoplasia leading to immunodeficiency; and hypocalcemia due to absent parathyroid glands. This chromosomal abnormality is associated with a highly variable phenotype. Characteristics include mild microcephaly, palatal clefting or incompetence, speech and language
1. Neurofibromatosis Type 1

Neurofibromatosis type 1 (NF-1) is one of the most common autosomal dominant disorders, occurring in 1 per 3000 births and seen in all races and ethnic groups. In general, the disorder is progressive, with new manifestations appearing over time. Neurofibromatosis type 2 (NF-2), characterized by bilateral acoustic neuromas, is a different disease caused by a different gene.

The gene for NF-1 is on the long arm of chromosome 17 and seems to code for a protein similar to a tumor suppressor factor. NF results from many different mutations of this gene. Approximately half of all NF cases are caused by new mutations. Careful evaluation of the parents is necessary to provide accurate genetic counseling. Recent evidence suggests that penetrance is close to 100% in those who carry one affected parent.

Café au lait macules may be present at birth, and about 80% of individuals with NF-1 will have more than six by age 1 year. Neurofibromas are benign tumors consisting of Schwann cells, nerve fibers, and fibroblasts; they may be discrete or plexiform. The incidence of Lisch nodules, which can be seen with a slit lamp, also increases with age. Affected individuals commonly have a large head, bony abnormalities on radiographic studies, scoliosis, and a wide spectrum of developmental problems. Although the average IQ is within the normal range, it is lower than in unaffected family members. (For more details of medical evaluation and treatment, see Chapter 25 of this book.) Useful information is provided on the following website: http://www.nfinc.org.

Hyperpigmented macules can occur in other conditions such as Albright, Noonan, Leopard, and Banayan-Riley-Ruvalcaba (BRR) syndromes. The genes for NF-1, Noonan, and Leopard syndromes are molecules which control cell cycling through the RAS-MAPK signal transduction pathways; therefore, it is not surprising that some features can be shared.

2. Marfan Syndrome

Genetic testing is available for mutations causing Marfan syndrome, but the diagnosis remains largely clinical and is based on the Ghent criteria (available at: http://www.gene-tests.org). Children most often present with a positive family history, suspicious skeletal findings, or ophthalmologic complications. Motor milestones are frequently delayed due to joint laxity and mild myopathy. Adolescents are prone to spontaneous pneumothorax. Dysrhythmias may be present. Aortic and valvular complications are not common in children but are more likely in sporadic cases. The characteristic facies is long and thin, with down-slanting palpebral fissures. The palate is high arched, and dentition is often crowded. The uvula may be bifid.

Marfan syndrome is genetically heterogeneous. Mutations in the gene for fibrillin-1 proteins (FBN1) are most common but mutations in (FBN2) and in transforming growth factor β receptors (TGFBR1 and 2) can also produce phenotypes that fit criteria for a clinical diagnosis of Marfan syndrome.

Differential Diagnosis

Homocystinuria should be excluded through metabolic testing in all individuals with marfanoid skeletal features. An X-linked recessive disorder, Lujan syndrome, combines marfanoid habitus with cognitive disability. Other connective tissue disorders, Ehlers-Danlos syndrome, and Stickler syndrome should also be considered.
Genes mutated in Marfan syndrome can also be mutated in related disorders: Beal syndrome (FBN2), Shprintzen-Goldberg syndrome (FBN1), and the recently described Loeys-Dietz syndrome (TGFBR1 and TGFBR2). The reader is referred to reviews available at http://www.genetests.org for descriptions of these disorders.

Complications
The skeletal problems including scoliosis are progressive. Astigmatism and myopia are very common and surveillance for lens dislocation is necessary.

The most serious associated medical problems involve the heart. Although many patients with Marfan syndrome have mitral valve prolapse, the most serious concern is progressive aortic root dilation, which may lead to aneurysmal rupture and death, and progressive or acute valvular (aortic more frequently than mitral) incompetency.

Families and practitioners seeking additional information about Marfan syndrome can be referred to the National Marfan Foundation (http://www.marfan.org).

Treatment
A. Medical Therapy
Medical treatment for patients with Marfan syndrome includes surveillance for and appropriate management of the ophthalmologic, orthopedic, and cardiac issues. Serial echocardiograms are indicated to diagnose and follow the degree of aortic root enlargement, which can be managed medically or surgically, in more severe cases. Prophylactic β-adrenergic blockade can slow the rate of aortic dilation and reduce the development of aortic complications.

Interest in the effects of deficient extracellular fibrillin-1 has led to the discovery that the mild myopathy in Marfan syndrome reflects excessive signaling by transforming growth factor β (TGFβ), an inhibitor of myoblast differentiation. Animal studies suggest that aortic aneurysm can be prevented by TGFβ antagonists, including blockers of angiotensin II type 1 receptors. Research studies are currently underway using this approach in human patients.

B. Genetic Counseling
Genetic testing for mutations in FBN1 and FBN2 and in TGFBR1 and TGFBR2 should be considered in all individuals with Marfan syndrome as penetrance is variable and apparently unaffected family members can carry and pass on mutations.

Achondroplasia, the most common form of skeletal dysplasia, is caused by a mutation in FGFR3.

Clinical Findings
The classic phenotype includes relative macrocephaly, midface hypoplasia, short-limbed dwarfism, and trident-shaped hands. The phenotype is apparent at birth. Individuals with achondroplasia are cognitively normal.

Treatment
A. Medical Therapy
Orthopedic intervention is necessary for spinal problems including severe lumbar lordosis and gibbus deformity. Long bone lengthening surgery may help to improve upper extremity function.

Head circumference during infancy must be closely monitored and plotted on a diagnosis-specific head circumference chart. Bony overgrowth at the level of the foramen magnum may lead to progressive hydrocephalus and brainstem compression, and may warrant neurosurgical intervention.

Many patients find support through organizations such as the Little People of America, at the following website: http://www.lpaonline.org.

B. Genetic Counseling
The vast majority of cases (approximately 90%) represent a new mutation. Two hemizygous parents with achondroplasia have a 25% risk of having a child homozygous for FGFR3 mutations, which is a lethal disorder.

4. Osteogenesis Imperfecta
Osteogenesis imperfecta (OI), or brittle bone disease, is a relatively common disorder. The more common forms are caused by mutations in type I collagen.

Clinical Findings
A number of types of OI have now been described, and abnormalities in Type I Collagen can now be tested via DNA analysis. The four most common types of OI are

1. Type I, a mild form, with increased incidence of fracturing and blue sclerae.
2. Type II, usually lethal in the newborn period with multiple congenital fractures and severe lung disease.
3. Type III, a severe form causing significant bony deformity secondary to multiple fractures (many of which are congenital), blue sclerae, short stature, and mild restrictive lung disease.
4. Type IV, another mild form with increased incidence of fracturing after birth; dentinogenesis imperfecta is common.
Treatment

A. Medical Therapy

A major advancement in the treatment of OI patients has been the use of pamidronate, and other bisphosphonate compounds, which have been reported to lead to a reduced incidence of fracture and improve bone density. Patients should be followed by an experienced orthopedist, as rodding of long bones and surgery to correct scoliosis are often required. Hearing assessments are indicated, because of the association between OI and deafness. Close dental follow-up is also necessary.

B. Genetic Counseling

The four main types of OI are associated with mutations in the genes coding for type I collagen. DNA analysis in blood can confirm the diagnosis. The milder forms may be seen as the result of dominant inheritance, while the more severe forms of OI generally result from new mutations.

5. Craniosynostosis Syndromes

The craniosynostosis disorders are common dominant disorders associated with premature fusion of cranial sutures. This class of disorders is usually caused by mutations in FGFR genes.

Crouzon syndrome is the most common of these disorders and is associated with multiple suture fusions, but with normal limbs. Other craniosynostosis disorders have limb as well as craniofacial anomalies, and include Pfeiffer, Apert, Jackson-Weiss, and Saethre-Chotzen syndromes.

Patients with craniosynostosis often have shallow orbits, midface narrowing that may result in upper airway obstruction, and hydrocephalus that may require shunting. Children with craniosynostosis may require multiple-staged craniofacial and neurosurgical procedures to address these issues, but usually have normal intelligence.

6. CHARGE Syndrome

CHARGE syndrome affects structures derived from rostral neural crest cells but also includes abnormal development of the eyes and midbrain. The acronym CHARGE serves as a mnemonic for associated abnormalities that include Colobomas, congenital Heart disease, choanal Atresia, growth Retardation, Genital abnormalities (hypogenitalism), and Ear abnormalities, with deafness. Facial asymmetry is a common finding. CHARGE is now known to be caused by mutations in the CHD7 gene on chromosome 8q. A website with information on CHARGE syndrome is available at http://www.chargesyndrome.org/.

7. Cornelia de Lange Syndrome

Cornelia de Lange syndrome is characterized by severe growth retardation; limb, especially hand, reduction defects (50%); congenital heart disease (25%); and stereotypical facies with hirsutism, medial fusion of eyebrows (synophrys), and thin, down-turned lips. The course and severity are variable, but the prognosis for survival and normal development is poor.

Heterozygous mutations in the cohesin regulator, NIPBL, or the cohesin structural components SMC1A and SMC3, have been identified in approximately 65% of individuals with CdLS. Cohesin regulates sister chromatid cohesion during mitosis and meiosis. In addition, cohesin has been demonstrated to play a critical role in the regulation of gene expression. Furthermore, multiple proteins in the cohesin pathway are also involved in additional fundamental biological events such as double-stranded DNA break repair, chromatin remodeling, and maintaining genomic stability.

8. Noonan Syndrome

Noonan syndrome is a common autosomal dominant disorder characterized by short stature, congenital heart disease, abnormalities of cardiac conduction and rhythm, webbed neck, down-slanting palpebral fissures, hearing loss, and low-set ears. The phenotype evolves with age and may be difficult to recognize in older patients. Mild developmental delays are often present. Recent advances in molecular genetic research have led to the definition of the RAS-mitogen-activated protein kinase (MAPK) pathway disorders or “RASopathies.” They comprise Noonan syndrome and related disorders (cardiofaciocutaneous and Costello syndromes), as well as neurofibromatosis type 1. A blood test that screens for the approximately 12 genes in this pathway is called a Noonan chip, and can help diagnose patients with Noonan syndrome and related disorders.

Products of proto-oncogenes help control cell cycling through RAS-MAPK signal transduction pathways. Cell cycling controls are also affected by mutations in other genes that produce more complicated Noonan-like disorders (ie, Costello and cardiofaciocutaneous syndromes) in which cardiomyopathies are prominent. Because mutations causing NF-1 also affect RAS proto-oncogene signaling, it is not surprising that there is an NF-1 subtype with a so-called Noonan phenotype.

Constitutional overactivation at various levels of the RAS-MAPK pathway causes overlapping syndromes, comprising characteristic facial features, cardiac defects, cutaneous
abnormalities, growth deficit, neurocognitive delay, and predisposition to malignancies. Each syndrome also exhibits unique features that probably reflect genotype-related specific biological effects.

AUTOSOMAL RECESSIVE DISORDERS

1. Cystic Fibrosis

The gene for cystic fibrosis, *CFTR*, is found on the long arm of chromosome 7. Approximately 1 in 22 persons are carriers. Many different mutations have been identified; the most common mutation in the Caucasian population is known as ΔF508.

Cloning of the gene for cystic fibrosis and identification of the mutation in the majority of cases have completely changed genetic counseling and prenatal diagnosis for this disorder, although the sweat chloride assay is still important in confirming the diagnosis.

The identification of the mutation in the cystic fibrosis gene has also raised the issue of mass newborn screening, because of the high frequency of this gene in the Caucasian population. Some states, such as Colorado, have offered newborn screening by trypsinogen assay, which can detect 70% of patients with cystic fibrosis. Although early detection can ensure good nutritional status starting at birth, newborn screening is controversial as there is no cure for cystic fibrosis. (For more details of medical management, see Chapters 19 and 22.)

2. Smith-Lemli-Opitz Syndrome

Smith-Lemli-Opitz syndrome is caused by a metabolic error in the final step of cholesterol production, resulting in low cholesterol levels and accumulation of the precursor 7-dehydrocholesterol (7-DHC). Because cholesterol is a necessary precursor for steroid hormones, bile acids and CNS myelin, and cholesterol content is crucial for the integrity of all cell membranes, the medical consequences of both cholesterol deficiency and 7-DHC accumulation are complex and severe. A number of other genetic disorders involving cholesterol biosynthesis more proximally in the pathway have been recently described (ie, Desmosterolosis), but are quite rare with a very severe and often lethal phenotype.

Clinical Findings

Patients with Smith-Lemli-Opitz syndrome present with a characteristic phenotype, including dysmorphic facial features (Figure 37–9), multiple congenital anomalies, hypotonia, growth failure, and intellectual disability. The diagnosis can be confirmed via a simple blood test looking for the presence of the precursor, 7-DHC. DNA analysis of mutations in the *DHR7* gene is also available. Prenatal testing is available.

Treatment

Treatment with cholesterol can ameliorate the growth failure and lead to improvement in medical issues, although treatment does not cure this complex disorder. Antioxidant treatment is being used to prevent progressive retinal degeneration.

3. Sensorineural Hearing Loss

Although there is marked genetic heterogeneity in causes of sensorineural hearing loss, including dominant, recessive, and X-linked patterns, nonsyndromic, recessively inherited deafness is the predominant form of severe inherited childhood deafness. Several hundred genes are known to
Duchenne muscular dystrophy (DMD) results from failure of synthesis of the muscle cytoskeletal protein dystrophin, the gene for which is located on the X chromosome, Xp12. Approximately 1 in 4000 male children is affected. Mutations in the same gene that result in partial expression of dystrophin protein produce a less severe phenotype, Becker muscular dystrophy (BMD). In both DMD and BMD, progressive degeneration of skeletal and cardiac muscle occurs. Boys with DMD exhibit proximal muscle weakness and pseudohypertrophy of calf muscles by age 5–6 years. Patients become nonambulatory by age 13. Serum creatine kinase levels are markedly elevated. Boys with DMD frequently die in their twenties of respiratory failure and cardiac dysfunction. The prognosis for BMD is more variable. Although corticosteroids are useful in maintaining strength, they do not slow progression of the disorder. Evolution of the natural history of dystrophinopathies in females is demonstrating an increased incidence of serious cardiovascular disease, including cardiomyopathy and arrhythmias.

The gene for dystrophin is very large and a common target for mutation. Large deletions or duplications can be detected in the gene for dystrophin in 65% of cases. Molecular analysis has largely replaced muscle biopsy for diagnostic purposes.

One-third of DMD cases presenting with a negative family history are likely to be new mutations. Genetic counseling is complicated by the fact that germline mosaicism for mutations in the dystrophin gene occur in approximately 15%–20% of families, which is among the highest rates for...
2. Hemophilia

Hemophilia A is an X-linked, recessive, bleeding disorder caused by a deficiency in the activity of coagulation factor VIII. Affected individuals develop a variable phenotype of hemorrhage into joints and muscles, easy bruising, and prolonged bleeding from wounds. The disorder is caused by heterogeneous mutations in the factor VIII gene, which maps to Xq28. Carrier detection and prenatal diagnosis are possible. Replacement of factor VIII is done using a variety of preparations derived from human plasma or recombinant techniques. Although replacement therapy is effective in most cases, 10%–15% of treated individuals develop neutralizing antibodies that decrease its effectiveness. (See Chapter 30 for additional discussion.)

3. Angelman Syndrome

Angelman syndrome also involves imprinting and results from a variety of mutations that inactivate a ubiquitin-protein ligase gene, UBE3A, located in the same region of chromosome 15 as SNRPN, the maternally imprinted gene involved in Prader-Willi syndrome (see the preceding section). UBE3A is paternally imprinted, and during normal development the maternal allele is expressed only in the brain. The classic phenotype includes severe intellectual disability with pronathism, seizures, and marked delay in motor milestones, abnormal gait and posturing, poor language development, autism, and paroxysmal laughter and tongue thrusting.

Angelman syndrome is most commonly caused when sequences detectable by microarray or FISH on 15q11 are deleted from the maternal homolog. Uniparental paternal disomy 15 is the least common cause. Mutations in UBE3A cause the disorder in about one-fourth of cases. Imprinting errors, which may be associated with advanced reproductive techniques, may also result in Angelman syndrome.

Children affected with BWS should undergo tumor surveillance protocols, including an abdominal ultrasound every 3 months until they reach age 8 years, as diagnosing malignancy at early stages leads to a significant improvement in outcome.

2. Prader-Willi Syndrome

Prader-Willi syndrome results from lack of expression of several imprinted genes, including SNRPN, located on chromosome 15q11. Clinical characteristics include severe hypotonia in infancy, often necessitating placement of a feeding gastrostomy tube. In older children, characteristic facies evolve over time, including almond-shaped eyes, along with frequent strabismus and obstructive sleep apnea. Short stature, obesity, hypogonitalism, and small hands and feet with tapering fingers are felt to be associated with growth hormone deficiency and GH treatment is now offered to PWS patients. Obsessive hyperphagia (usual onset 3–4 years) is the hallmark of this disorder.

Deletion of the paternally inherited allele of chromosome 15q11 (detected by FISH or microarray) is the most common chromosomal abnormality causing Prader-Willi syndrome, followed by maternal UPD, diagnosed by DNA methylation studies.
DISORDERS ASSOCIATED WITH ANTICIPATION

1. (Autosomal Dominant) Myotonic Dystrophy

Myotonic dystrophy is an autosomal dominant condition characterized by muscle weakness and tonic muscle spasms (myotonia). Additional features include: hypogonadism, frontal balding, cardiac conduction abnormalities, and cataracts. This disorder occurs when a CTG repeat in the DMPK gene on chromosome 19 expands to 50 or more copies. Normal individuals have from 5 to 35 CTG repeat copies. Individuals carrying 35–49 repeats are generally asymptomatic, but repeat copies greater than 35 are meiotically unstable and tend to further expand when passed to subsequent generations. Individuals with 50–100 copies may be only mildly affected (eg, cataracts). Most individuals with repeat copies greater than 100 will have symptoms or electrical myotonia as adults.

As unstable alleles continue to expand and copy numbers approach 400, symptoms become evident in children. Expansion from greater than 1000 copies produces fetal and neonatal disease that can be lethal. This occurs most frequently when the unstable repeats are passed through an affected mother. Therefore, an important component in the workup of the floppy or weak infant is a careful neurologic assessment of both parents for evidence of weakness or myotonia. Molecular testing that measures the number of CTG repeats is diagnostic clinically and prenatally. (See Chapter 25 for additional discussion.)

2. (Autosomal Recessive) Friedreich Ataxia

Symptoms of Friedreich ataxia include loss of coordination (cerebellar dysfunction) with both motor and sensory findings beginning in preadolescence and typically progressing through the teenage years. The gene involved, FDRA, is located on chromosome 9. Normal individuals carry 7–33 GAA repeats at this locus. Close to 96% of affected patients are homozygous for repeat expansions that exceed 66 copies. However, point mutations in the gene also occur. Meiotic instability for GAA repeats is more variable than for others and contractions occur more frequently than do expansions. Relationships between genotype and phenotype are also more complex. Molecular diagnostic testing requires careful interpretation with respect to prognosis and reproductive risks. (See Chapter 25 for additional discussion.)

3. (X-Linked) Fragile X Syndrome

Fragile X syndrome, present in approximately 1 in 1000 males, is the most common cause of cognitive disabilities in males. The responsible gene is FMR1, which has unstable CGG repeats at the 5’ end. Normal individuals have up to 50 CGG repeats. Individuals with 51–200 CGG repeats have a premutation and may manifest symptoms including developmental, behavioral, and physical traits; premature ovarian failure in a subset of females; and a progressive, neurologic deterioration in older males called FXTAS (Fragile X–associated tremor–ataxia syndrome). Affected individuals with Fragile X syndrome (full mutation) have more than 200 CGG repeats and also have hypermethylation of both the CGG expansion and an adjacent CpG island. This methylation turns off the FMR1 gene. DNA analysis, rather than cytogenetic testing, is the method of choice for confirming the diagnosis of Fragile X syndrome.

Clinical Features

Most males with Fragile X syndrome present with intellectual disabilities, oblong faces with large ears, and large testicles after puberty. Other physical signs include symptoms suggestive of a connective tissue disorder (eg, hyperextensible joints or mitral valve prolapse). Many affected individuals are hyperactive and exhibit behaviors along the autism spectrum.

Unlike other X-linked disorders where female heterozygotes are asymptomatic, females with a full mutation may exhibit a phenotype ranging from normal IQ to intellectual disability, and autism, and may manifest other behavioral problems.

Clinical expression of Fragile X differs in male and female offspring depending on which parent is transmitting the gene. The premutation can change into the full mutation only when passed through a female. Identification of the abnormal DNA amplification by direct DNA analysis can confirm the diagnosis of Fragile X in an affected individual and can detect asymptomatic gene carriers of both sexes. Therefore, DNA analysis is a reliable test for prenatal and postnatal diagnosis of Fragile X syndrome and facilitates genetic counseling. (Management considerations for patients with Fragile X syndrome are described in Chapter 3.)

MITochondRIAL DISORDERS

More than 100 point mutations and rearrangements of mtDNA have been identified, which are associated with a large number of human diseases. Symptoms of mitochondrial disorders are secondary to deficiency in the respiratory chain enzymes of oxidative phosphorylation, which supply energy to all cells. Mitochondrial diseases are usually progressive disorders with neurologic dysfunction including hypotonia, developmental delay, and seizures. Ophthalmologic issues, hearing loss, gastrointestinal tract dysfunction with growth failure, and renal, endocrine, cardiac, and autonomic dysfunction are some of the many issues which can affect patients with mitochondrial diseases. The following disorders are three of the more common ones.
1. MELAS
MELAS is an acronym for Mitochondrial Encephalopathy, Lactic Acidosis, and Strokelike episodes. Symptoms occur in the pediatric age group and include recurrent episodes resembling stroke (blindness, paralysis), headache, vomiting, weakness of proximal muscles, and elevated blood lactate. (Note: Lactate may be falsely elevated secondary to technical difficulties in obtaining a free-flowing blood specimen or delay in laboratory measurement.) The most common mutation causing MELAS is in the tRNA<sup>Leu</sup> gene (A3243G).

2. MERRF
MERRF is an acronym for Myoclonus Epilepsy with Ragged Red Fibers. Children with MERRF present with a variety of neurologic symptoms, including myoclonus, deafness, weakness of muscles, and seizures. Eighty percent of cases are due to a missense mutation in the mitochondrial tRNALys gene (A8344G).

3. Leigh Subacute Necrotizing Encephalomyelopathy
Multiple different abnormalities in respiratory chain function lead to Leigh disease, a very severe disorder associated with progressive loss of developmental milestones, along with extrapyramidal symptoms and brainstem dysfunction. Episodes of deterioration are frequently associated with an intercurrent febrile illness. Symptoms include hypotonia, unusual choreoathetoid hand movements, feeding dysfunction with failure to thrive, and seizures. Focal necrotic lesions of the brainstem and thalamus are hallmarks on MRI scan. Mitochondrial mutations affecting the respiratory chain, especially complexes I, II, and IV, and nuclear DNA mutations affecting complex II have been identified as causing Leigh disease.

- Cleft lip and palate may be isolated defects (nonsyndromic) or associated with other anomalies as part of a genetic disorder (syndromic).
- Pierre Robin sequence, the association of cleft palate, micrognathia, and glossoptosis may lead to severe airway complications in young infants, necessitating tracheostomy.

General Considerations
From a genetic standpoint, cleft lip with or without cleft palate is distinct from isolated cleft palate. Although both can occur in a single family, particularly in association with certain syndromes, this pattern is unusual. Racial background is a factor in the incidence of facial clefting. Among Asians, Caucasians, and blacks, the incidence is 1.61, 0.9, and 0.31, respectively, per 1000 live births.

Findings
A cleft lip may be unilateral or bilateral and complete or incomplete. It may occur with a cleft of the entire palate or just the primary (anterior and gingival ridge) or secondary (posterior) palate. An isolated cleft palate can involve only the soft palate or both the soft and hard palates. It can be a V-shaped or a wide horseshoe, U-shaped cleft. When the cleft palate is associated with micrognathia and glossoptosis (a tongue that falls back and causes respiratory or feeding problems), it is called the Pierre Robin sequence. Among individuals with facial clefts—more commonly those with isolated cleft palate—the incidence of other congenital abnormalities is increased, with up to a 60% association with other anomalies or syndromes. The incidence of congenital heart disease, for example, is 1%–2% in liveborn infants, but among those with Pierre Robin sequence it can be as high as 15%. Associated abnormalities should be looked for in the period immediately after birth and before surgery.

Differential Diagnosis
A facial cleft may occur in many different circumstances. It may be an isolated abnormality or part of a more generalized syndrome. Prognosis, management, and accurate determination of recurrence risks all depend on accurate diagnosis. In evaluating a child with a facial cleft, the physician must determine if the cleft is nonsyndromic or syndromic.

A. Nonsyndromic
In the past, nonsyndromic cleft lip or cleft palate was considered a classic example of polygenic or multifactorial inheritance. Several recent studies have suggested that one or more major autosomal loci, both recessive and dominant may be involved. Empirically, however, the recurrence risk is
Table 37-4. Syndromic isolated cleft palate (CP) and cleft lip with or without cleft palate (CL/CP).

still in the range of 2%–3% because of nonpenetrance or the presence of other contributing genes.

B. Syndromic

Cleft lip, with or without cleft palate, and isolated cleft palate may occur in a variety of syndromes that may be environmental, chromosomal, single gene, or of unknown origin (Table 37–4). Prognosis and accurate recurrence risks depend on the correct diagnosis.

Complications

Problems associated with facial clefts include early feeding difficulties, which may be severe; airway obstruction necessitating tracheostomy; recurrent serous otitis media associated with fluctuating hearing and language delays; speech problems, including language delay, hypernasality, and articulation errors; and dental and orthodontic complications.

Treatment

A. Medical Therapy

Long-term management ideally should be provided through a multidisciplinary cleft palate clinic.

B. Genetic Counseling

Accurate counseling depends on accurate diagnosis and the differentiation of syndromic from nonsyndromic clefts. A complete family history must be taken, and the patient and both parents must be examined. The choice of laboratory studies is guided by the presence of other abnormalities and clinical suspicions, and may include microarray analysis and metabolic and DNA studies. Clefts of both the lip and the palate can be detected on detailed prenatal ultrasound.

NEURAL TUBE DEFECTS

- Various defects, ranging from anencephaly to open or skin-covered lesions of the spinal cord, may occur in isolation or as part of a syndrome.
- Myelomeningocele is usually associated with hydrocephalus, Arnold-Chiari II malformation, neurogenic bladder and bowel, and congenital paralysis in the lower extremities.
- Anomalies of the CNS, heart, and kidneys may also be seen.
- MRI helps determine the extent of the anatomic defect in skin covered lesions.

General Considerations

Neural tube defects comprise a variety of malformations, including anencephaly, encephalocele, spina bifida (myelomeningocele), sacral agenesis, and other spinal dysraphisms. Evidence suggests that the neural tube develops via closure at multiple closure sites and that each closure site is mediated by different genes and affected by different teratogens. Hydrocephalus associated with the Arnold-Chiari type II malformation commonly occurs with myelomeningocele. Sacral agenesis, also called the caudal regression syndrome, occurs more frequently in infants of diabetic mothers.

Clinical Findings

At birth, neural tube defects can present as an obvious rachischisis (open lesion), or as a more subtle skin-covered lesion. In the latter case, MRI should be conducted to better define the anatomic defect. The extent of neurologic deficit depends on the level of the lesion and may include clubfeet, dislocated hips, or total flaccid paralysis below the level of the lesion. Hydrocephalus may be apparent at birth or may develop after the back has been surgically repaired. Neurogenic bladder and bowel are commonly seen. Other anomalies of the CNS may be present, as well as anomalies of the heart or kidneys.

Differential Diagnosis

Neural tube defects may occur in isolation (nonsyndromic) or as part of a genetic syndrome. They may result from teratogenic exposure to alcohol or the anticonvulsant valproate.
Any infant with dysmorphic features or other major anomalies in addition to a neural tube defect should be evaluated by a geneticist, and a microarray analysis should be performed.

- **Treatment**

  **A. Neurosurgical Measures**
  
  Infants with an open neural tube defect should be placed in prone position, and the lesion kept moist with sterile dressing. Neurosurgical closure should occur within 24–48 hours after birth to reduce risk of infection. The infant should be monitored closely for signs of hydrocephalus. Shunts are required in about 85% of cases of myelomeningocele and are associated with complications including malfunction and infection. Symptoms of the Arnold-Chiari II malformation include feeding dysfunction, abducens nerve palsy, vocal cord paralysis with stridor, and apnea. Shunt malfunction may cause an acute worsening of Arnold-Chiari symptoms that may be life-threatening.

- **B. Orthopedic Measures**
  
  The child’s ability to walk varies according to the level of the lesion. Children with low lumbar and sacral lesions walk with minimal support, while those with high lumbar and thoracic lesions are rarely functional walkers. Orthopedic input is necessary to address foot deformities and scoliosis. Physical therapy services are indicated.

- **C. Urologic Measures**
  
  Neurogenic bladders have variable presentations. Urodynamic studies are recommended early on to define bladder function, and management is guided by the results of these studies. Continence can often be achieved by the use of anticholinergic or sympathomimetic agents, clean intermittent catheterization, and a variety of urologic procedures. Renal function should be monitored regularly, and an ultrasound examination should be periodically repeated. Symptomatic infections should be treated.

  Symptoms of neurogenic bowel include incontinence and chronic constipation and are managed with a combination of dietary modifications, laxatives, stool softeners, and rectal stimulation. A surgical procedure called ACE (ante-grade continence enema) may be recommended for patients with severe constipation that is unresponsive to conservative management.

- **D. Genetic Counseling**
  
  Most isolated neural tube defects are polygenic, with a recurrence risk of 2%–3% in future pregnancies. The recurrence risk for siblings of the parents and siblings of the patients is 1%–2%. A patient with spina bifida has a 5% chance of having an affected child. Prenatal diagnosis is possible. In fetuses with open neural tube defects, maternal serum α-fetoprotein levels measured at 16–18 weeks’ gestation are elevated. α-Fetoprotein and acetylcholine esterase levels in amniotic fluid are also elevated. Ultrasound studies alone can detect up to 90% of neural tube defects.

  Prophylactic folic acid can significantly lower the incidence and recurrence rate of neural tube defects, if the intake of the folic acid starts at least 3 months prior to conception and continues for the first month of pregnancy, at a dose of 4 mg/d for women at increased risk. For women of childbearing age without a family history of neural tube defects, the dose is 0.4 mg of folic acid daily. Folic acid supplementation prior to conception may also lower the incidence of other congenital malformations such as conotruncal heart defects.

- **Special Issues & Prognosis**

  All children requiring multiple surgical procedures (ie, patients with spina bifida or urinary tract anomalies) have a significant risk for developing hypersensitivity type I (IgE-mediated) allergic reactions to latex. For this reason, nonlatex medical products are now routinely used when caring for patients with neural tube defects.

  Most individuals with spina bifida are cognitively normal, but learning disabilities are common. Individuals with encephalocele or other CNS malformations generally have a much poorer intellectual prognosis. Individuals with closed spinal cord abnormalities (eg, sacral lipomas) have more mild issues in general, and intelligence is usually normal. Spinal cord tethering may present later with symptoms of back pain, progressive scoliosis, and changes in bowel or bladder function. This often requires neurosurgical intervention.

  Individuals with neural tube defects have lifelong medical issues, requiring the input of a multidisciplinary medical team. A good support for families is the National Spina Bifida Association, at the following website: http://www.sbba.org.

### COMMON RECOGNIZABLE DISORDERS WITH VARIABLE OR UNKNOWN CAUSE

The text that follows describes several important and common human malformation syndromes. The best illustrations of these syndromes are found in Smith’s Recognizable Patterns of Human Malformation. An excellent Internet site at the University of Kansas Medical Center can be consulted for further information: http://www.kumc.edu/gec/support.

#### 1. Arthrogryposis Multiplex

The term *arthrogryposis* is often used as shorthand to describe multiple congenital contractures that affect two or more different areas of the body. Arthrogryposis is not a specific diagnosis, but rather a clinical finding, and it is a characteristic of more than 300 different disorders. Causes most often involve constraint, CNS maldevelopment or injury,
and neuromuscular disorders. Polyhydramnios is often present as a result of lack of fetal swallowing. Pulmonary hypoplasia may also be present, reflecting lack of fetal breathing. The workup includes brain imaging, careful consideration of metabolic disease, neurologic consultation, and, in some cases, electrophysiologic studies and muscle biopsy. The parents should be examined, and a family history reviewed carefully for findings such as muscle weakness or cramping, cataracts, and early-onset heart disease, suggesting myotonic dystrophy. Mutations in at least five genes (TNNI2, TNNT3, TPM2, MYH3, and MYH8) that encode components of the contractile apparatus of fast-twitch myofibers can cause distal arthrogryposis.

2. Goldenhar Syndrome

Goldenhar syndrome, also known as vertebral-auriculofacial syndrome, is an association of multiple anomalies involving the head and neck. The classic phenotype includes hemifacial microsomia (one side of the face smaller than the other), and abnormalities of the pinna on the same side with associated deafness. EAR anomalies may be quite severe and include anotia. A characteristic benign fatty tumor in the outer eye, called an epibulbar dermoid, is frequently present, as are preauricular ear tags. Vertebral anomalies, particularly of the cervical vertebrae, are common. The Arnold-Chiari type I malformation (herniation of the cerebellum into the cervical spinal canal) is a common associated anomaly. Cardiac anomalies and hydrocephalus are seen in more severe cases. Most patients with Goldenhar syndrome have normal intelligence. The cause is unknown; however, there is significant overlap with the Townes-Brocks syndrome, caused by mutations in the SALL1 gene. (See Craniofacial Microsomia Overview, GeneReviews, www.genereviews.org for an excellent discussion and differential diagnosis.)

3. Oligohydramnios Sequence (Potter Sequence)

This condition presents in newborns as severe respiratory distress due to pulmonary hypoplasia in association with positional deformities of the extremities, usually bilateral clubfeet, and typical facies consisting of suborbital creases, depressed nasal tip and low-set ears, and retrognathia. The sequence may be due to prolonged lack of amniotic fluid. Most often it is due to leakage, renal agenesis, or severe obstructive uropathy.

4. Overgrowth Syndromes

Overgrowth syndromes are becoming increasingly recognized as important childhood conditions. They may present at birth and are characterized by macrocephaly, motor delays (cerebral hypotonia), and occasional asymmetry of extremities. Bone age may be advanced. The most common overgrowth syndrome is Sotos syndrome. Patients with Sotos syndrome have a characteristic facies with a prominent forehead and down-slanting palpebral features. Mutations in NSD1 cause Sotos syndrome. Patients have a small but increased risk of cancer.

Other overgrowth syndromes include BWS (described earlier), and two single-gene disorders, Simpson-Golabi-Behmel syndrome and Bannayan-Riley-Ruvalcaba syndrome. Patients with Simpson-Golabi-Behmel syndrome exhibit a BWS-like phenotype, but with additional anomalies, including polydactyly and more severe facial dysmorphisms. Unlike patients with BWS, who have normal intelligence, patients with Simpson-Golabi-Behmel syndrome often have developmental delay. It is inherited as an X-linked disorder. Patients with Bannayan-Riley-Ruvalcaba syndrome have macrosomia, macrocephaly, and unusual freckling of the penis. They may present with autism. They may develop hemangiomatous or lymphangiomatous growths and have a predisposition to certain malignancies (thyroid, breast, colon cancer). The cause of Bannayan-Riley-Ruvalcaba syndrome is a mutation of the PTEN gene implicated in Cowden syndrome, the association of intestinal polyposis with malignant potential. Proteus syndrome was recently found to be caused by mosaic AKT-1 mutation.

5. Syndromic Short Stature

Short stature is an important component of numerous syndromes, or it may be an isolated finding. In the absence of nutritional deficiencies, endocrine abnormalities, evidence of skeletal dysplasia (disproportionate growth with abnormal skeletal films), or a positive family history, intrinsic short stature can be due to UPD. The phenotype of Russell-Silver syndrome—short stature with normal head growth (pseudohydradcephalus), normal development, and minor dysmorphic features (especially fifth finger clinodactyly)—has been associated in some cases with maternal UPD7.

6. VACTERL Association

The disorder is sporadic, and some of the defects may be life-threatening. The prognosis for normal development is good. The cause is unknown, but a high association with monozygotic twinning suggests a mechanism dating back to events perhaps as early as blastogenesis.

Careful examination and follow-up are important, because numerous other syndromes have overlapping features. Microarray studies and genetic consultation are warranted.
VACTERL association is described by an acronym denoting the association of the following:
- Vertebral defects (segmentation anomalies).
- Imperforate anus.
- Cardiac malformation (most often ventricular septal defect).
- Tracheoesophageal fistula.
- Renal anomalies.
- Limb (most often radial ray) anomalies.

### 7. Kabuki syndrome

Kabuki syndrome (KS) is characterized by typical facial features (elongated palpebral fissures with eversion of the lateral third of the lower eyelid; arched and broad eyebrows; short columella with depressed nasal tip; large, prominent, or cupped ears), minor skeletal anomalies, persistence of fetal fingertip pads, mild to moderate intellectual disability, and postnatal growth deficiency. Other findings may include: congenital heart defects, genitourinary anomalies, cleft lip and/or palate, gastrointestinal anomalies including anal atresia, ptosis and strabismus, and widely spaced teeth and hypodontia. Functional differences can include increased susceptibility to infections and autoimmune disorders, seizures, endocrinologic abnormalities including isolated premature thelarche in females, feeding problems, and hearing loss. Molecular genetic testing for MLL2, the only gene in which mutations are known to cause KS, is available on a clinical basis. The cause is heterogeneous, as not all individuals with Kabuki syndrome were found to have a MLL2 mutation.

### GENETIC EVALUATION OF THE CHILD WITH DEVELOPMENTAL DISABILITIES

Cognitive disabilities or developmental delays affect 8% of the population. Disorders associated with symptoms of delayed development are heterogeneous but frequently include heritable components. Evaluation should be multidisciplinary; Table 37–5 lists the main features of developmental delay, emphasizing the major clinical and genetic considerations. (See Chapter 3 for additional information about developmental delay and intellectual disability.)

### Table 37–5. Evaluation of the child with developmental delay.

| Consanguinity |  |

| Physical examination |  |
| General pediatric examination, including growth parameters |  |
| Focused dysmorphologic evaluation including measurement of facial features and limbs |  |
| Complete neurologic examination |  |
| Parental growth parameters (especially head circumferences) and dysmorphic features should also be assessed |  |

| Imaging studies |  |
| See text |  |

| Laboratory assessment |  |
| Microarray analysis (this has replaced chromosome analysis and FISH testing in most cases) |  |
| Fragile X testing (analysis of FMR1 gene for triplet repeats) |  |
| Other blood analyses: comprehensive metabolic panel, acylcarnitine profile, creatinine kinase (CK), lactate, pyruvate (this testing is helpful in the case of hypotonia) |  |
| Other metabolic tests may be helpful as second tier tests, including: Serum amino acid analysis |  |
| Urine amino and organic acid analysis |  |
| Urine analysis for mucopolysaccharides (if coarse features and organomegaly) |  |

Obtaining a detailed history, including pertinent prenatal and perinatal events, is critical. Feeding issues and slow growth velocity are seen in many genetic disorders causing developmental delay. Rate of developmental progress and particularly a history of loss of skills are important clues, as the latter might suggest a metabolic disorder with a neurodegenerative component. Family history can provide clues to suggest possible genetic etiologies, particularly if there is a history of consanguinity or a family pattern of other affected individuals.

Physical examination provides helpful clues. Referral to a clinical geneticist is indicated whenever unusual features are encountered. Neurologic, ophthalmologic, and audiologic
consultation should be sought when indicated. Brain imaging should be requested in cases involving unexplained deviations from normal head growth. Neuroimaging and skeletal studies may also be indicated when dysmorphic features are present.

Metabolic and genetic testing procedures other than those listed in the Table 37–5 may also be indicated.

**Interpretation & Follow-Up**

Clinical experience indicates that specific diagnoses can be made in approximately half of patients evaluated according to the protocol presented here. With specific diagnosis comes prognosis, ideas for management, and insight into recurrence risks. Prenatal diagnosis may also become possible.

Follow-up is important both for patients in whom diagnoses have been made and for those patients initially lacking a diagnosis. Genetic information is accumulating rapidly and can be translated into new diagnoses and better understanding with periodic review of clinical cases.

**Autism**

Autism is a developmental disorder comprising abnormal function in three domains: language development, social development, and behavior. Many patients with autism also have cognitive disabilities and might be appropriately evaluated according to the recommendations above. However, given the enormous increase in prevalence of autism in the past decade (1 in 88 children per latest CDC report), it is worth discussing the genetic evaluation of autism separately.

There are multiple known genetic causes of autism. Advances in molecular diagnosis, understanding of metabolic derangements, and technologies such as microarray are allowing more patients with autism to be identified with specific genetic disorders. This allows more accurate genetic counseling for recurrence risk, as well as diagnosis-specific interventions which may improve prognosis.

With this in mind, recommendations for the genetic evaluation of a child with autism include the following:

1. Genetic referral if dysmorphic features or cutaneous abnormalities are present (ie, hypopigmented spots such as those seen in patients with tuberous sclerosis).
2. Laboratory testing to include the following:
   A. Microarray.
   B. Molecular testing for Fragile X syndrome.
   C. Methylation testing for UPD15 if phenotype is suggestive of Angelman syndrome.
   D. Measurement of cholesterol and 7-DHC if syndactyly is present between the second and third toes, to rule out a mild form of Smith-Lemli-Opitz syndrome.
   E. MECP2 testing if clinical course is suggestive of Rett syndrome (ie, neurodegenerative course, progressive microcephaly, and seizures in a female patient).
   F. PTEN molecular testing if the head circumference is greater than 2 standard deviations above the mean, plus evidence of penile freckling, lipomatous lesions, or a strong family history of certain malignancies.

Autism spectrum disorders are discussed in more detail in Chapter 3.

**TERATOGENS**

1. **Drug Abuse & Fetal Alcohol Syndrome**

Fetal alcohol syndrome (FAS) results from excessive exposure to alcohol during gestation and affects 30%–40% of offspring of mothers whose daily intake of alcohol exceeds 3 ounces. Features of the syndrome include: short stature, poor head growth (may be postnatal in onset), developmental delay, and midface hypoplasia characterized by a poorly developed long philtrum, narrow palpebral fissures, and short nose with anteverted nares. Facial findings may be subtle, but careful measurements and comparisons with standards (see Figure 37–8) are helpful. Structural abnormalities occur in half of affected children. Cardiac anomalies and neural tube defects are commonly seen. Genitourinary tract anomalies are frequent. Neurobehavioral effects in FAS include: poor judgment and inappropriate social interactions, and lack of stranger anxiety in toddlers. Cognitive deficiencies and behavioral problems may occur without other classic physical characteristics of fetal alcohol syndrome and constitute an alcohol-related neurological disorder (ARND).

Maternal abuse of psychoactive substances is also associated with increased risks for adverse perinatal outcomes including miscarriage, preterm delivery, growth retardation, and increased risk for injury to the developing CNS. Methamphetamine and crack cocaine are particularly dangerous. Maternal abuse of inhalants, such as glue, appears to be associated with findings similar to those of fetal alcohol syndrome.

Careful evaluation for other syndromes and chromosomal disorders should be included in the workup of exposed infants. Behavioral abnormalities in older children may be the result of maternally abused substances but they may also reflect evolving psychiatric disorders. Psychiatric disorders, many recognized as heritable, affect large numbers of men and women with substance abuse problems. Fetal alcohol spectrum disorders are discussed in more detail in Chapter 3.

2. **Maternal Anticonvulsant Effects**

Anticonvulsant exposure during pregnancy is associated with adverse outcomes in approximately 10% of children born to women treated with these agents. A syndrome
characterized by small head circumference, antverted nares, cleft lip and palate (occasionally), and distal digital hypoplasia was first described in association with maternal use of phenytoin but also occurs with other anticonvulsants. Risks for spina bifida are increased, especially in pregnancies exposed to valproic acid.

3. Retinoic Acid Embryopathy

Vitamin A and its analogs are potent morphogens that have considerable teratogenic potential. Developmental toxicity occurs in approximately one-third of pregnancies exposed in the first trimester to the synthetic retinoid isotretinoin, commonly prescribed to treat acne. Exposure disrupts migration of rostral neural crest cells and produces CNS maldevelopment, especially of the posterior fossa; ear anomalies (often absence of pinnae); congenital heart disease (great vessel anomalies); and tracheoesophageal fistula. These findings constitute a partial phenocopy of DiGeorge syndrome and demonstrate the continuum of contributing genetic and environmental factors in morphogenesis. It is now recognized that vitamin A itself, when taken as active retinoic acid in doses exceeding 25,000 IU/d during pregnancy, can produce similar fetal anomalies. Vitamin A intake is limited to 10,000 IU/d of retinoic acid. Maternal ingestion of large amounts of vitamin A taken as retinol during pregnancy, however, does not increase risks, because conversion of this precursor to active retinoic acid is internally regulated.

ASSISTED REPRODUCTION

Assisted reproductive technologies including in vitro fertilization are now utilized in a significant number of pregnancies. Although healthy live births are accepted as the usual outcomes resulting from successful application of these procedures, the actual number of viable embryos is limited and questions about the risks of adverse effects continue to be raised. Increased rates of twinning, both monozygotic and dizygotic, are well recognized while the possibility of increased rates of birth defects remains controversial. Abnormal genetic imprinting appears to be associated with in vitro fertilization. Evidence supports increased prevalence of Beckwith-Wiedemann and Angelman syndromes among offspring of in vitro pregnancies.

PRENATAL DIAGNOSIS

Prenatal screening for birth defects is now routinely offered to pregnant women of all ages. Prenatal diagnosis introduces options for management.

Prenatal assessment of the fetus includes techniques that screen maternal blood, image the conceptus, fetal DNA analysis via maternal serum samples, and samples of fetal and placental tissues.

Maternal Blood Analysis

Elevated levels of maternal serum $\alpha$-fetoprotein correlate with open neural tube defects but low levels are associated with Down syndrome and other chromosomal abnormalities. First trimester measurements of PAPA (pregnancy-associated plasma protein A) and the free $\beta$-subunit of human chorionic gonadotropin screen for trisomies 21 and 18. In the second trimester maternal $\alpha$-fetoprotein, human chorionic gonadotropin, unconjugated estradiol, and inhibin (“quad screen”) combine to estimate risks for trisomies 21 and 18. Low estradiol levels can also predict cases of Smith-Lemli-Opitz syndrome, a devastating autosomal recessive disorder discussed earlier. Noninvasive prenatal testing, via maternal blood sample, can detect specific chromosome imbalances. Massive parallel sequencing technology is applied to the circulating cell free DNA in maternal samples. The detection rate is higher than traditional first trimester screening.

Analysis of Fetal Samples

A. Amniocentesis

Amniocentesis samples fluid surrounding the fetus; the cells obtained are cultured for cytogenetic, molecular, or metabolic analyses. $\alpha$-Fetoprotein and other chemical markers can also be measured. This is a safe procedure with a complication rate (primarily for miscarriage) of less than 0.01% in experienced hands.

B. Chorionic Villus Sampling (Placental)

Chorionic villus sampling is generally performed at 10–12 weeks’ gestation. Tissue obtained by chorionic villus sampling provides DNA for molecular analysis and contains dividing cells (cytotrophoblasts) that can be rapidly evaluated by FISH. However, direct cytogenetic preparations may be of poor quality and placental fibroblasts must be routinely grown and analyzed. In addition, chromosomal abnormalities detected by this technique may be confined to the placenta (confined placental mosaicism) and be less informative than amniocentesis.

C. Fetal Blood and Tissue

Fetal blood can be sampled directly in late gestation through ultrasound-guided percutaneous umbilical blood sampling (PUBS). A wide range of diagnostic tests ranging from biochemical to comparative genomic hybridization can be applied. Fetal urine sampled from the bladder or dilated proximal structures can provide important information about fetal renal function.

It is occasionally necessary to obtain biopsy specimens of fetal tissues such as liver or muscle for accurate prenatal diagnosis. These procedures are available in only a few perinatal centers.
D. Preimplantation Genetic Diagnosis

With the advent of single-cell PCR techniques as well as interphase FISH it is now possible to make genetic diagnoses in preimplantation human embryos by removing and analyzing blastocyst cells. Using this procedure parents can now consider selecting pregnancies for positive attributes such as becoming donors for transplantation of tissues to siblings affected by genetic disorders.

Fetal Imaging

Fetal ultrasonography has become routine and MRI imaging is becoming increasingly common during pregnancy, while fetal x-rays are seldom employed. Ultrasonography has joined maternal blood sampling as a screening technique for common chromosomal aneuploidies, neural tube defects, and other structural anomalies. Pregnancies at increased risk for CNS anomalies, skeletal dysplasias, and structural defects of the heart and kidneys should be monitored by careful ultrasound examinations. Fetal MRI has become routine in the workup of suspected fetal CNS abnormalities as well as in an increasing number of other fetal anomalies.
Allergic disorders are among the most common problems seen by pediatricians and primary care physicians, affecting over 25% of the population in developed countries. In the most recent National Health and Nutrition Examination Survey, 54% of the population had positive test responses to one or more allergens. According to a recent National Center for Health Statistics survey, the prevalence of food and skin allergies has increased over the past decade; with prevalence in 2009–2011 of 5% and 12.5%, respectively. While the prevalence of respiratory allergies has been stable, it is still the highest among children (17% in 2009–2011). In children, asthma, allergic rhinitis, and atopic dermatitis have been accompanied by significant morbidity and school absenteeism, with adverse consequences for school performance and quality of life, as well as economic burden measured in billions of dollars. In this chapter, atopy refers to a genetically determined predisposition to develop IgE antibodies found in patients with asthma, allergic rhinitis, and atopic dermatitis.

**ASTHMA**

**General Considerations**

Asthma is the most common chronic disease of childhood, affecting over 7 million children in the United States. While current prevalence rates for asthma have increased in the past decade (most recent estimate of 10%), the rate of asthma attack in the past year has been stable. Gender, race, and socioeconomic disparities in the prevalence of asthma exist: (1) More boys than girls are affected in childhood; (2) Higher percentage affected among black children compared to Hispanic and non-Hispanic white children; (3) Children belonging to poor families are more likely to be affected.

There is still a disproportionately higher healthcare utilization for asthma among children compared to adults affected by this disease. Asthma health care encounters in primary care settings have increased over time; death rates and emergency department (ED) visits related to asthma have declined, and hospitalizations due to asthma have been steady. Hospitalizations and emergency department or urgent ambulatory or office visits, all indicators of asthma severity, impose significant costs to the healthcare system and to families, caretakers, schools, and parents’ employers. Indirect costs primarily from loss of productivity due to school/work absences are harder to measure, yet considerable. Asthma remains a potentially life-threatening disease for children; the rate of asthma deaths was 28 per 1 million children with current asthma. Similar to disparities in prevalence, morbidity and mortality rates for asthma are higher among minority and inner city populations. The reasons for this are unclear but may be related to a combination of more severe disease, poor access to health care, lack of asthma education, delay in use of appropriate controller therapy, and environmental factors (eg, irritants including smoke and air pollutants, and perennial allergen exposure).

Up to 80% of children with asthma develop symptoms before their fifth birthday. Atopy (personal or familial) is the strongest identifiable predisposing factor. Sensitization to inhalant allergens increases over time and is found in the majority of children with asthma. The principal allergens associated with asthma are perennial aeroallergens such as dust mite, animal dander, cockroach, and *Alternaria* (a soil mold). Rarely, foods may provoke isolated asthma symptoms.

About 40% of infants and young children who have wheezing with viral infections in the first few years of life will have continuing asthma through childhood. Viral infections (eg, respiratory syncytial virus [RSV], rhinovirus, parainfluenza and influenza viruses, metapneumovirus) are associated with wheezing episodes in young children. RSV may be the predominant pathogen of wheezing infants in the emergency room setting, but rhinovirus can be detected in the majority of older wheezing children. Furthermore, RSV...
and parainfluenza have been associated with more severe respiratory illnesses, but in general, rhinovirus is the most commonly identified respiratory virus with wheezing episodes. It is uncertain if these viruses contribute to the development of chronic asthma, independent of atopy. Severe RSV bronchiolitis in infancy has been linked to asthma and allergy in childhood. Although speculative, individuals with lower airways vulnerability to common respiratory viral pathogens may be at risk for persistent asthma.

In addition to atopy and infections being associated with the development of asthma, observational studies have also demonstrated an increased risk of asthma attributed to acetaminophen exposure during prenatal periods, infancy, childhood, and even adulthood. Acetaminophen is the most commonly used antipyretic medication for children in the United States. Furthermore, there is evidence from secondary analyses suggesting that acetaminophen exposure increases the risk for subsequent asthma exacerbations or wheeze compared to ibuprofen; and that a dose dependent elevated risk of asthma symptoms could be found.

There are several mechanisms which have been proposed: acetaminophen interfering with glutathione (a tripeptide antioxidant that is involved in free radical scavenging and xenobiotic detoxification) pathway and impairing respiratory antioxidant defenses; presence of genetic polymorphisms in the glutathione pathway that are associated with increased susceptibility to asthma; and acetaminophen causing a switch to a TH2 from a TH1 response. Stronger pieces of evidence such as prospectively designed studies primarily addressing the questions of whether acetaminophen exposure truly increases the risk of the development of chronic asthma or even triggers acute asthma are needed.

Exposure to tobacco smoke, especially from the mother, is also a risk factor for asthma. Other triggers include exercise, cold air, cigarette smoke, pollutants, strong chemical odors, and rapid changes in barometric pressure. Aspirin sensitivity is uncommon in children. Psychological factors may precipitate asthma exacerbations and place the patient at high risk from the disease.

Pathologic features of asthma include shedding of airway epithelium, edema, mucus plug formation, mast cell activation, and collagen deposition beneath the basement membrane. The inflammatory cell infiltrate includes eosinophils, lymphocytes, and neutrophils, especially in fatal asthma exacerbations. Airway inflammation contributes to airway hyperresponsiveness, airflow limitation, and disease chronicity. Persistent airway inflammation can lead to airway wall remodeling and irreversible changes.

Clinical Findings

A. Symptoms and Signs

The diagnosis of asthma in children, especially among preschool aged, is based largely on clinical judgment and an assessment of symptoms, activity limitation, and quality of life. For example, if a child with asthma refrains from participating in physical activities so as not to trigger asthma symptoms, their asthma would be inadequately controlled but not detected by the standard questions. In the National Asthma Education and Prevention Program (NAEPP) clinical guidelines, asthma control is introduced as an approach to assess the adequacy of current treatment, and to improve care and outcomes for children with asthma. For children with asthma, numerous validated instruments and questionnaires for assessing health-related quality of life and asthma control have been developed. The Asthma Control Test (ACT, www.asthmacontrol.com), the Asthma Control Questionnaire (ACQ, www.qoltech.co.uk/Asthma1.htm), and the Asthma Therapy Assessment Questionnaire (ATAQ, www.ataqinstrument.com) for children 12 years of age and older, and the Childhood ACT for children 4–11 years of age are examples of self-administered questionnaires that have been developed with the objective of addressing multiple aspects of asthma control such as frequency of daytime and nocturnal symptoms, use of reliever medications, functional status, missed school or work, and so on. A five-item caregiver-administered instrument, the Test for Respiratory and Asthma Control in Kids (TRACK), has been validated as a tool to assess both impairment and risk presented in the NAEPP Expert Panel Report 3 (EPR3) guidelines in young children with recurrent wheezing or respiratory symptoms consistent with asthma.

Wheezing is the most characteristic sign of asthma, although some children may have recurrent cough and shortness of breath. Complaints may include “chest congestion,” prolonged cough, exercise intolerance, dyspnea, and recurrent bronchitis or pneumonia. Chest auscultation during forced expiration may reveal prolongation of the expiratory phase and wheezing. As the obstruction becomes more severe, wheezes become more high-pitched and breath sounds diminished. With severe obstruction, wheezes may not be heard because of poor air movement. Flaring of nostrils, intercostal and suprasternal retractions, and use of accessory muscles of respiration are signs of severe obstruction. Cyanosis of the lips and nail beds may be seen with underlying hypoxia. Tachycardia and pulsus paradoxus also occur. Agitation and lethargy may be signs of impending respiratory failure.

B. Laboratory Findings

Bronchial hyperresponsiveness, reversible airflow limitation, and airway inflammation are key features of asthma. Documentation of all these components is not always necessary, unless the presentation is rather atypical.

Bronchial hyperresponsiveness to nonspecific stimuli is a hallmark of asthma. These stimuli include inhaled pharmacologic agents such as histamine, methacholine, and mannitol, as well as physical stimuli such as exercise and cold air. Mannitol (Aridol) bronchoprovocation has been approved
During acute asthma exacerbations, FEV1 is diminished and can be measured by reduction in FEV1 and FEV1/FVC values, in the evaluation of airflow limitation in asthma. This spirometry over peak expiratory flow rate (PEFR) measurement may help to establish a diagnosis of asthma when the history, with the severity of asthma. Bronchoprovocation challenges The level of airway hyperresponsiveness usually correlates younger than age 5 years is greater than in older children. The level of airway hyperresponsiveness usually correlates with the severity of asthma. Bronchoprovocation challenges may help to establish a diagnosis of asthma when the history, examination, and pulmonary function tests are not definitive.

Recent asthma clinical guidelines reinforce the use of spirometry over peak expiratory flow rate (PEFR) measurements, in the evaluation of airflow limitation in asthma. This can be measured by reduction in FEV1 and FEV1/FVC values compared to reference or predicted values. By itself, it is not adequate in establishing a diagnosis, but it can be an important parameter to monitor asthma activity and treatment response. In children, FEV1 may be normal, despite frequent symptoms. Spirometric measures of airflow limitation can be associated with symptom severity, likelihood of exacerbation, hospitalization, or respiratory compromise. Regular monitoring of prebronchodilator (and ideally postbronchodilator) FEV1 can be used to track lung growth patterns over time. During acute asthma exacerbations, FEV1 is diminished and the flow-volume curve shows a “scooping out” of the distal portion of the expiratory portion of the loop (Figure 38–1).

Lung function assessment using body box plethysmography to determine lung volume measurements can also be informative. The residual volume, functional residual capacity, and total lung capacity are usually increased, while the vital capacity is decreased. Reversal or significant improvement of these abnormalities in response to inhaled bronchodilator therapy or with anti-inflammatory therapy can be observed.

PEFR monitoring can be a simple and reproducible tool to assess asthma activity in children with moderate or severe asthma, a history of severe exacerbations, or poor perception of airflow limitation or worsening condition. Significant changes in PEFR may occur before symptoms become evident. In more severe cases, PEFR monitoring enables earlier recognition of suboptimal asthma control.

Infant pulmonary function can be measured in sedated children with compression techniques. The forced oscillation technique can be used to measure airway resistance even in younger children.

Hypoxemia is present early with a normal or low PaCO2 level and respiratory alkalosis. Hypoxemia may be aggravated during treatment with a β2-agonist due to ventilation-perfusion mismatch. Oxygen saturation less than 91% is indicative of significant obstruction. Respiratory acidosis and increasing CO2 tension may ensue with further air-flow obstruction and signal impending respiratory failure. Hypercapnia is usually not seen until the FEV1 falls below 20% of predicted value. Metabolic acidosis has also been noted in combination with respiratory acidosis in children with severe asthma and indicates imminent respiratory failure. PaO2 less than 60 mm Hg despite oxygen therapy and PacO2 over 60 mm Hg and rising more than 5 mm Hg/h are relative indications for mechanical ventilation in a child in status asthmaticus.

Pulsus paradoxus may be present with moderate or severe asthma exacerbation. In moderate asthma exacerbation in a child, this may be between 10 and 25 mm Hg, and in severe asthma exacerbation between 20 and 40 mm Hg. Absence of pulsus paradoxus in a child with severe asthma exacerbation may signal respiratory muscle fatigue.

Clumps of eosinophils on sputum smear and blood eosinophilia are frequent findings. Their presence tends to reflect disease activity and does not necessarily mean that allergic factors are involved. Leukocytosis is common in acute severe asthma without evidence of bacterial infection and may be more pronounced after epinephrine administration. Hematocrit can be elevated with dehydration during prolonged exacerbations or in severe chronic disease. Noninvasive measures of airway inflammation include exhaled nitric oxide concentrations, serum eosinophil cationic protein levels, and induced sputum. Each test has its strengths and weaknesses.

C. Imaging

Evaluation of asthma usually does not need chest radiographs (posteroanterior and lateral views) since they often
appear normal, although subtle and nonspecific findings of hyperinflation (flattening of the diaphragms), peribronchial thickening, prominence of the pulmonary arteries, and areas of patchy atelectasis may be present. Atelectasis may be misinterpreted as the infiltrates of pneumonia. Some lung abnormalities, such as bronchiectasis, which may point to a different diagnosis implicating an asthma masquerader, such as cystic fibrosis, allergic bronchopulmonary mycoses (aspergillosis), ciliary dyskinesias, or immune deficiencies, can be better appreciated with high-resolution, thin-section chest computed tomography (HRCT) scans. It is primarily useful clinically in ruling out certain diagnoses in patients with difficult to manage asthma but radiation exposure should be considered when ordering HRCT.

Allergy testing is discussed in the section on General Measures under Treatment, Chronic Asthma.

Differential Diagnosis

Diseases that may be mistaken for asthma are often related to the patient’s age (Table 38–1). Congenital abnormalities must be excluded in infants and young children. Asthma can be confused with croup, acute bronchiolitis, pneumonia, and pertussis. Immunodeficiency may be associated with cough and wheezing. Foreign bodies in the airway may cause dyspnea or wheezing of sudden onset, and on auscultation, wheezing may be unilateral. Asymmetry of the lungs secondary to air trapping may be seen on a chest radiograph, especially with forced expiration. Cystic fibrosis can be associated with or mistaken for asthma.

Vocal cord dysfunction is an important masquerader of asthma, although the two can coexist. It is characterized by the paradoxical closure of the vocal cords that can result in dyspnea and wheezing. Diagnosis is made by direct visualization of the vocal cords. In normal individuals, the vocal cords abduct during inspiration and may adduct slightly during expiration. Asthmatic patients may have narrowing of the glottis during expiration as a physiologic adaptation to airway obstruction. In contrast, patients with isolated vocal cord dysfunction typically show adduction of the anterior two-thirds of their vocal cords during inspiration, with a small diamond-shaped aperture posteriorly. Because this abnormal vocal cord pattern may be intermittently present, a normal examination does not exclude the diagnosis. Bronchial challenges using exercise or methacholine can precipitate symptoms of vocal cord dysfunction. The flow-volume loop may provide additional clues to the diagnosis of vocal cord dysfunction. Truncation of the inspiratory portion can be demonstrated in most patients during an acute episode, and some patients continue to show this pattern even when they are asymptomatic (see Figure 38–1). Children with vocal cord dysfunction, especially adolescents, tend to be overly competitive, primarily in athletics and scholastics. A psychiatric consultation may help define underlying psychological issues and provide appropriate therapy. Treatment of isolated vocal cord dysfunction includes education regarding the condition and appropriate breathing exercises. Hypnosis, biofeedback, and psychotherapy have been effective for some patients.

Table 38–1. Differential diagnosis of asthma in infants and children.

to the consequences of illness denial, poor coping or self-management skills, as well as to nonadherence with prescribed therapy. Recent studies have shown that less than 50% of inhaled asthma medications are taken as prescribed and that compliance does not improve with increasing severity of illness. Moreover, children requiring hospitalization for asthma, or their caregivers, have often failed to institute appropriate home treatment.

Complications

With acute asthma, complications are primarily related to hypoxemia and acidosis and can include generalized seizures. Pneumomediastinum or pneumothorax can be a complication in status asthmaticus. With chronic asthma, recent studies point to airway wall remodeling and loss of pulmonary function with persistent airway inflammation. Childhood asthma independent of any corticosteroid therapy has been shown to be associated with delayed maturation and slowing of prepubertal growth velocity.

Treatment

A. Chronic Asthma

1. General measures—Optimal asthma management includes an assessment and regular monitoring of disease activity, education and partnership to improve the child’s and his/her family’s knowledge and skills for self-management, identification and management of triggers and conditions that may worsen asthma, and appropriate medications selected to address the patient’s needs. The objective of asthma management is the attainment of the best possible asthma control.

An assessment of asthma severity (ie, the intrinsic intensity of disease) is generally most accurate in patients not receiving controller therapy. Hence, assessing asthma severity directs the level of initial therapy. For those already on treatment, asthma severity can be classified according to the level of medication requirement to maintain adequate asthma control. The two general categories are intermittent and persistent asthma, the latter further subdivided into mild, moderate, and severe (Table 38–2). In contrast, asthma control refers to the degree to which symptoms, ongoing functional impairments, and risk of adverse events are minimized and goals of therapy are met. Assessment of asthma control should be done at every visit as this is important in adjusting therapy. It is categorized as “well controlled,” “not well controlled,” and “very poorly controlled” (Table 38–3). Responsiveness to therapy is the ease with which asthma control is attained by treatment. It can also encompass monitoring for adverse effects related to medication use.

Classification of either asthma severity or control is based on the domains of current impairment and risk, recognizing that these domains may respond differently to treatment. The level of asthma severity or control is established upon the most severe component of impairment or risk. Generally, the assessment of impairment is symptom based, except for the use of lung function for school-aged children and youths. Impairment includes an assessment of the patient’s recent symptom frequency and intensity and functional limitations (ie, daytime symptoms, nighttime awakenings, need for short-acting β₂-agonists for quick relief, work or school days missed, ability to engage in normal or desired activities, and quality-of-life assessments) and airflow compromise preferably using spirometry. On the other hand, risk refers to an evaluation of the patient’s likelihood of developing asthma exacerbations, reduced lung growth in children (or progressive decline in lung function in adults), or risk of untoward effects from medications.

Education is important and partnership with the child’s family is a key component in the management to improve adherence and outcomes. The patient and family must understand the role of asthma triggers, the importance of disease activity even without obvious symptoms, how to use objective measures to gauge disease activity, and the importance of airway inflammation—and they must learn to recognize the warning signs of worsening asthma, allowing for early intervention. A stepwise care plan should be developed for all patients with asthma. Providing asthma action plans is currently a requirement that is tracked by many hospitals and others to document that educational instruction for chronic disease management has been given. Asthma action plans should be provided to school personnel and all those who care for children with asthma.

Because the degree of airflow limitation is poorly perceived by many patients, peak flow meters can aid in the assessment of airflow obstruction and day-to-day disease activity. Peak flow rates may provide early warning of worsening asthma. They are also helpful in monitoring the effects of medication changes. Spacer devices optimize delivery of medication from metered-dose inhalers (MDIs) to the lungs and, with inhaled steroids, minimize side effects. Large-volume spacers are preferred. Poor understanding by patients and families of proper device use can lead to inadequate delivery and treatment with inhaled medications, especially inhaled controllers. Short instructive videos for device use can be provided to educate families and other caregivers (URL: http://www.thechildrenshospital.org/conditions/lung/asthmavideos.aspx).

Patients should avoid exposure to tobacco smoke and allergens to which they are sensitized, exertion outdoors when levels of air pollution are high, β-blockers, and sulfite-containing foods. Patients with persistent asthma should be given the inactivated influenza vaccine yearly unless they have a contraindication.

For patients with persistent asthma, the clinician should use the patient’s history to assess sensitivity to seasonal allergens and Alternaria mold; use in vitro testing (either by skin or blood test) to assess sensitivity to perennial indoor
Table 38–2. Assessing severity and initiating treatment for patients who are not currently taking long-term control medications.

Notes:
- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- Level of severity is determined by both impairment and risk. Assess impairment domain by patient’s/caregiver’s recall of previous 2–4 weeks. Symptom assessment for longer periods should reflect a global assessment such as inquiring whether a patient’s asthma is better or worse since the last visit. Assign severity to the most severe category in which any feature occurs.

- Maintain current step.
- Regular follow-up every 1–6 mo to maintain control.
- Consider step-down if well controlled for at least 3 mo.
- Step up (1 step) and reevaluate in 2–6 wk.
- If no clear benefit in 4–6 wk consider alternative diagnoses or adjusting therapy.
- For side effects, consider alternative options.
- Consider short course of oral corticosteroids.
- Step up (1–2 steps), and reevaluate in 2 wk.
- If no clear benefit in 4–6 wk, consider alternative diagnoses or adjusting therapy.
- For side effects, consider alternative options.

**Notes:**
- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- The level of control is based on the most severe impairment or risk category. Assess impairment domain by caregiver’s recall of previous 2–4 weeks. Symptom assessment for longer periods should reflect a global assessment such as inquiring whether the patient’s asthma is better or worse since the last visit.
- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma control. In general, more frequent and intense exacerbations (eg, requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate poorer disease control. For treatment purposes, patients who had ≥ 2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have not-well-controlled asthma, even in the absence of impairment levels consistent with not-well-controlled asthma.
- Validated questionnaires for the impairment domain (the questionnaires do not assess lung function or the risk domain):
  a. ATAQ = Asthma Therapy Assessment Questionnaire
  b. ACQ = Asthma Control Questionnaire
  c. ACT = Asthma Control Test
  d. Minimal Important Difference: 1.0 for ATAQ; 0.5 for the ACQ; not determined for ACT; *ACQ values of 0.76–1.40 are indeterminate regarding well-controlled asthma.
- Before step-up therapy:
  a. Review adherence to medications, inhaler technique, and environmental control.
  b. If alternative treatment option was used in a step, discontinue it and use preferred treatment for that step. EIB, exercise-induced bronchospasm; FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity.

Allergens; assess the significance of positive tests in the context of the patient’s history; and identify relevant allergen exposures. For dust mite–allergic children, important environmental control measures include encasing the pillow and mattress in an allergen-impermeable cover and washing the sheets and blankets on the patient’s bed weekly in hot water. Other measures include keeping indoor humidity below 50%, minimizing the number of stuffed toys, and washing such toys weekly in hot water. Children allergic to fur-bearing animals or feathers should avoid indoor exposure to pets, especially for prolonged periods of time. If removal of the pet is not possible, the animal should be kept out of the bedroom with the door closed. Carpeting and upholstered furniture should be removed. While a high-efficiency particle-arresting filter unit in the bedroom may reduce allergen levels, symptoms may persist if the pet remains indoors. For cockroach–allergic children, control measures need to be instituted when infestation is present in the home. Poison baits, boric acid, and traps are preferred to chemical agents, which can be irritating if inhaled by asthmatic individuals. Indoor molds are especially prominent in humid or damp environments. Measures to control dampness or fungal growth in the home may be of benefit. Patients can reduce exposure to outdoor allergens by staying in an air-conditioned environment. Allergen immunotherapy may be useful for implicated aeroallergens that cannot be avoided. However, it should be administered only in facilities staffed and equipped to treat life-threatening reactions.

Patients should be treated for rhinitis, sinusitis, or gastro-esophageal reflux, if present. Treatment of upper respiratory tract symptoms is an integral part of asthma management. Intranasal corticosteroids are recommended to treat chronic rhinosinusitis in patients with persistent asthma because they reduce lower airway hyperresponsiveness and asthma symptoms. Intranasal cromolyn reduces asthma symptoms.
during the ragweed season but less so than intranasal corticosteroids. Treatment of rhinosinusitis includes medical measures to promote drainage and the use of antibiotics for acute bacterial infections (see Chapter 18). Medical management of gastroesophageal reflux includes avoiding eating or drinking 2 hours before bedtime, elevating the head of the bed with 6- to 8-in blocks, and using appropriate pharmacologic therapy.

2. Pharmacologic therapy—A revised stepwise approach to pharmacologic therapy, broken down by age categories, is recommended in the NAEPP EPR3 (http://www.nhlbi.nih.gov) (Table 38–4). This approach is based on the concepts of asthma severity and asthma control. A separate set of recommendations for younger children is provided given the lack of tools which can be used to assess lung function and quality of life otherwise available for older children. Treatment recommendations for older children and adults are better supported by stronger evidence from available clinical trials, whereas those for younger children have been extrapolated from studies in older children and adults.

The choice of initial therapy is based on assessment of asthma severity. For patients who are already on controller therapy, treatment can be adjusted based on assessment of asthma control and responsiveness to therapy. The goals of therapy are to reduce the components of both impairment (eg, preventing chronic and troublesome symptoms, allowing infrequent need of quick-relief medications, maintaining “normal” lung function, maintaining normal activity levels including physical activity and school attendance, meeting families’ expectations and satisfaction with asthma care) and risk (eg, preventing recurrent exacerbations, reduced lung growth, and medication adverse effects).

1. The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.

2. In the absence of persistent symptoms, the new clinical guidelines recommend considering initiation of long-term controller therapy for infants and younger children who have risk factors for asthma (ie, modified asthma predictive index: parental history of asthma, physician-diagnosed atopic dermatitis, or sensitization to Aeroallergens or two of the following: wheezing apart from colds, sensitization to foods, or peripheral eosinophilia) and four or more episodes of wheezing over the past year that lasted longer than 1 day and affected sleep or two or more exacerbations in 6 months requiring systemic corticosteroids.

3. Inhaled corticosteroids, either as monotherapy or in combination with adjunctive therapy, are preferred treatment for all levels of persistent asthma.

4. Along with medium-dose inhaled corticosteroids, combination therapy with inhaled corticosteroids plus any of the following adjunctive therapies—long-acting inhaled β₂-agonists (LABAs), leukotriene modifying agents, cromones, and theophylline—is recommended as step 3 treatment for moderate persistent asthma, or as step-up therapy for uncontrolled persistent asthma for school-aged children and youths. In children aged 0–4 years, medium-dose inhaled corticosteroids as monotherapy remain the step 3 therapy, and combination therapy to be initiated only as a step 4 treatment. A rescue course of systemic corticosteroids may be necessary at any step.

Asthma medications are classified as long-term controller medications and quick-relief medications. The former includes anti-inflammatory agents, leukotriene modifiers, and long-acting bronchodilators. Although LABAs (salmeterol, formoterol) are β₂-agonists, they are considered to be daily controller medications, but unlike the other asthma controller medications with primarily anti-inflammatory properties, LABAs cannot be administered as monotherapy.

Inhaled corticosteroids are the most potent inhaled anti-inflammatory agents currently available. Different inhaled corticosteroids are not equivalent on a per puff or microgram basis (Table 38–5). Early intervention with inhaled corticosteroids can improve asthma control and prevent exacerbations during treatment, but they do not prevent the development of persistent asthma nor do they alter its natural history. Long-term inhaled corticosteroids may be associated with early slowing of growth velocity in children, and although this can impact the final adult height by a minimum degree, it is not a cumulative effect. Possible risks from inhaled corticosteroids need to be weighed against the risks from undertreated asthma. The adverse effects from inhaled corticosteroids are generally dose and duration dependent, so that greater risks for systemic adverse effects are expected with high doses. The various inhaled corticosteroids are delivered in different devices such as MDI (beclomethasone, ciclesonide, fluticasone, flunisolide, and triamcinolone), dry powder inhaler (DPI) (fluticasone [Diskus], budesonide [Flexhaler], and mometasone [Twisthaler]), and nebulized aerosol suspensions (budesonide respules). Inhaled medications delivered in MDI now use the more ozone friendly hydrofluoroalkane (HFA) propellant, which has replaced chlorofluorocarbons (CFC). See instructions for different device use at the following URL: http://www.thechildrenshospital.org/conditions/lung/asthmaideos.aspx.

Only inhaled corticosteroids have been shown to be effective in long-term clinical studies with infants. Nebulized budesonide is approved for children as young as 12 months. The suspension (available in quantities of 0.25 mg/2 mL, 0.5 mg/2 mL, and 1.0 mg/2 mL) is usually administered either once or twice daily in divided doses. For effective drug delivery, it is critical that the child has a mask secured on the face for the entire treatment, as blowing it in the face is not effective and yet a common practice by parents. Notably, this drug should not be given by ultrasonic nebulizer.
Table 38-4. Stepwise approach for managing asthma in children.

Each step: Patient education, environmental control, and management of comorbidities.

Age ≥ 5 y: Steps 2–4: Consider subcutaneous allergen immunotherapy for patients who have allergic asthma.

Quick-Relief Medication for All Patients
- SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms: up to three treatments at 20-minute intervals as needed. Short course of oral systemic corticosteroids may be needed.
- Caution: Use of SABA > 2 d/wk for symptom relief (not prevention of EIB) generally indicates inadequate control and the need to step up treatment.
- For ages 0–4 years: With viral respiratory infection: SABA q4-6h up to 24 hours (longer with physician consult). Consider short course of systemic corticosteroids if exacerbation is severe or patient has history of previous severe exacerbations.

Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy.

Notes:
- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- If clear benefit is not observed within 4–6 weeks and patient/family medication technique and adherence are satisfactory, consider adjusting therapy or alternative diagnosis.
Table 38-4. Stepwise approach for managing asthma in children. (Continued)

- Studies on children aged 0–4 years are limited. Step 2 therapy is based on Evidence A. All other recommendations are based on expert opinion and extrapolation from studies in older children.
- For age 5–11 years, steps 1 and 2 medications are based on Evidence A. Step 3 ICS + adjunctive therapy and ICS are based on Evidence B for efficacy of each treatment and extrapolation from comparator trials in older children and adults—comparator trials are not available for this age group; steps 4–6 are based on expert opinion and extrapolation from studies in older children and adults.
- For ages ≥ 12 years, steps 1, 2, and 3 preferred therapies are based on Evidence A; step 3 alternative therapy is based on Evidence A for LTRA, Evidence B for theophylline, and Evidence D for zileuton. Step 4 preferred therapy is based on Evidence B, and alternative therapy is based on Evidence B for LTRA and theophylline and Evidence D for zileuton. Step 5 preferred therapy is based on Evidence B. Step 6 preferred therapy is based on (EPR-1 1997) and Evidence B for omalizumab. In step 6, before oral systemic corticosteroids are introduced, a trial of high-dose ICS + LABA + either LTRA, theophylline, or zileuton may be considered, although this approach has not been studied in clinical trials.
- Clinicians who administer immunotherapy or omalizumab should be prepared and equipped to identify and treat anaphylaxis that may occur.
- Theophylline is a less desirable alternative due to the need to monitor serum concentration levels.
- Zileuton is less desirable alternative due to limited studies as adjunctive therapy and the need to monitor liver function.
- Immunotherapy for steps 2–4 is based on Evidence B for house dust mites, animal danders, and pollens; evidence is weak or lacking for molds and cockroaches. Evidence is strongest for immunotherapy with single allergens. The role of allergy in asthma is greater in children than in adults.
- ICS, inhaled corticosteroid; LABA, inhaled long-acting β₂-agonist; LTRA, leukotriene receptor antagonist; prn, as needed; SABA, inhaled short-acting β₂-agonist.

Limited data suggest that inhaled corticosteroids may be effective even in very young children when delivered by MDI with a spacer and mask.

Fewer data are available with nedocromil, although data from the Childhood Asthma Management Program study showed that an inhaled corticosteroid was superior to nedocromil with respect to several efficacy parameters, including rate of hospitalization, symptom-free days, need for albuterol rescue, and longer time to treatment with prednisone, when each was compared to a placebo.

Theophylline is rarely used. Sustained-release theophylline, an alternative long-term control medication for older children, may have particular risks of adverse effects in infants, who frequently have febrile illnesses that increase theophylline concentrations. Hence, if theophylline is used, it requires monitoring of serum concentration to prevent numerous dose-related acute toxicities.

For school aged children whose asthma is uncontrolled on low dose inhaled corticosteroid (ie, requiring step 3 guidelines therapy), majority are likely to respond to a step up combination therapy with a long-acting β₂-agonist bronchodilator (eg, salmeterol and formoterol), although some respond best either to an increased dose of inhaled corticosteroid or to an addition of a leukotriene receptor antagonist. LABAs should not be used for treatment of acute symptoms, nor should they be used without any inhaled corticosteroid therapy, even if the patient feels better. Salmeterol is available as an inhalation powder (one inhalation twice daily for patients aged 4 years and older). It is also available combined with fluticasone (50 mcg salmeterol with 100, 250, or 500 mcg fluticasone in a DPI or 21 mcg salmeterol with 45, 115, or 230 mcg fluticasone in an MDI). For children 12 years and older, one inhalation DPI or two inhalations MDI can be taken twice daily. (Note: The 100/50 fluticasone/salmeterol combination is approved in children aged 4 and older.) Salmeterol can also be used 30 minutes before exercise (but not in addition to regularly used LABAs). Formoterol has a more rapid onset of action and is available singly as a DPI (Aerolizer, 12 mcg) or combined with an inhaled corticosteroid (formoterol fumarate, either 4.5 mcg with budesonide [80 or 160 mcg] or 5 mcg with mometasone [100 or 200 mcg], in an MDI). Formoterol DPI is approved for use in children 5 years and older, one inhalation (12 mcg) twice daily, while the combination product is approved for children 12 years and older, two inhalations twice daily. For long-term control, formoterol should be used in combination with an anti-inflammatory agent. It can be used for exercise-induced bronchospasm in patients 5 years and older, one inhalation at least 15 minutes before exercise (but not in addition to regularly used LABAs). Of note, the U.S. Food and Drug Administration (FDA) has requested the manufacturers of Advair Diskus and HFA (salmeterol and fluticasone), Serevent Diskus (salmeterol xinafoate), Foradil Aerolizer (formoterol fumarate), Symbicort HFA, and Brovana (arformoterol tartrate inhalation solution, a LABA approved for chronic obstructive pulmonary disease) to update their product information warning sections regarding an increase in severe asthma episodes associated with these agents. This action is in response to data showing an increased number of asthma-related deaths in patients receiving LABA therapy in addition to their usual asthma care as compared with patients not receiving LABAs. This notice is also intended to reinforce the appropriate use of LABAs in the management of asthma. Specifically, LABA products should not be initiated as first-line asthma therapy, used with worsening wheezing, or used for acute control of bronchospasm. No data are available regarding safety concerns in patients using these products for exercise-induced bronchoconstriction. Additional information, including copies of the Patient and Healthcare Professional information sheets, can be found at: http://www.fda.gov/cder/drug/infopage/LABA/default.htm.

Montelukast and zafirlukast are leukotriene-receptor antagonists available in oral formulations. Montelukast is given once daily and has been approved for treatment of chronic asthma in children aged 1 year and older, as an alternative step 2 monotherapy and add-on therapy for steps 3–6. It is also indicated for seasonal allergic rhinitis in patients 2 years and older, and for perennial allergic rhinitis in patients 6 months and older. To date, no drug interactions have been noted. The dosage is 4 mg for children 1–5 years (oral granules are available for children aged 12–23 months), 5 mg for children aged 6–14 years, and 10 mg for those aged 15 years and older. The drug is given without regard to mealtimes, preferably in the evening. Zafirlukast is approved for patients aged 5 years and older. The dose is 10 mg twice daily for those 5–11 years and 20 mg twice daily for those 12 years and older. It should be taken 1 hour before or 2 hours after meals. Zileuton is a 5-lipoxygenase inhibitor indicated for chronic treatment in children 12 years of age and older, available in regular 600 mg dose tablet four times a day or extended release 600 mg dose tablet, 2 tablets twice a day. Patients need to have hepatic transaminase levels evaluated at initiation of therapy, then once a month for the first 3 months, every 2–3 months for the remainder of the first year, and periodically thereafter if receiving long-term zileuton therapy. Rare cases of Churg-Strauss syndrome have been reported in adult patients with severe asthma whose steroid dosage was being tapered during concomitant treatment with leukotriene-receptor antagonists (as well as inhaled corticosteroids), but no causal link has been established. Both zafirlukast and zileuton are microsomal P-450 enzyme inhibitors that can inhibit the metabolism of drugs such as warfarin and theophylline. The FDA has requested that manufacturers include a precaution in the drug prescribing information (drug labeling) regarding neuropsychiatric events (agitation, aggression, anxiety, dream abnormalities and hallucinations, depression,
insomnia, irritability, restlessness, suicidal thinking and behavior, and tremor) based on postmarket reports of patients taking leukotriene modifying agents. Of note, in a study of children with mild to moderate persistent asthma that looked at whether responses to an inhaled corticosteroid and a leukotriene-receptor antagonist are concordant for individuals or whether asthmatic patients who do not respond to one medication respond to the other, response to fluticasone and montelukast were found to vary considerably. Children with low pulmonary function or high levels of markers associated with allergic inflammation responded better to the inhaled corticosteroid.

Children with persistent asthma who remain uncontrolled on inhaled corticosteroid monotherapy are more likely to respond to a combination treatment of an inhaled corticosteroid and a LABA; however, there are children who can respond best to a higher dose of inhaled corticosteroid, or even a low dose inhaled corticosteroid plus montelukast. It has not been definitely determined what clinical features would be helpful in selecting the most appropriate medication for any one patient. Recent studies in adults have also shown the efficacy of a long-acting antimuscarinic medication for any one patient. Recent studies in adults or even a low dose inhaled corticosteroid plus montelukast. It has not been definitely determined what clinical features would be helpful in selecting the most appropriate medication for any one patient. Recent studies in adults have also shown the efficacy of a long-acting antimuscarinic agent, tiotropium (Spiriva), as an add-on therapy to inhaled corticosteroids. Quick-relief medications include short-acting inhaled β₂-agonists (SABAs) such as albuterol, levalbuterol, pirbuterol, or terbutaline. Albuterol can be given by nebulizer, 0.05 mg/kg (with a minimal dose of 0.63 mg and a maximum of 5 mg) in 2–3 mL saline (although it is also available in a 2.5 mg/3 mL single vial or 5 mg/mL concentrated solution) or by MDI (90 mcg/actuation). It is better to use SABAs as needed rather than on a regular basis. Increasing use, including more than one canister per month, may signify inadequate asthma control and the need to step up or revise controller therapy. Levalbuterol, the (R)-enantiomer of racemic albuterol, is available in solution for nebulization in patients aged 6–11 years, 0.31 mg every 8 hours, and in patients 12 years and older, 0.63–1.25 mg every 8 hours. It has recently become available in an HFA formulation for children 4 years and older, two inhalations (90 mcg) every 4–6 hours as needed. Anticholinergic agents such as ipratropium, 1–3 puffs or 0.25–0.5 mg by nebulizer every 6 hours, may provide additive benefit when used together with an inhaled SABA. Systemic corticosteroids such as prednisone, prednisolone, and methylprednisolone can be given in a dosage of 1–2 mg/kg, usually not to exceed 60 mg/d in single or divided doses for 3–10 days. There is no evidence that tapering the dose following a “burst” prevents relapse.

Anti-IgE (omalizumab) is a recombinant DNA-derived humanized IgG1 monoclonal antibody that selectively binds to human IgE. It inhibits the binding of IgE to the high-affinity IgE receptor (FcεRI) on the surface of mast cells and basophils. Reduction in surface-bound IgE on FcεRI-bearing cells limits the degree of release of mediators of the allergic response. Treatment with omalizumab also reduces the number of FcεRI receptors on basophils in atopic patients. Omalizumab is indicated for patients 12 years of age and older with moderate to severe persistent asthma who have a positive skin test or in vitro reactivity to a perennial aeroallergen with total serum IgE of 30–700 IU/mL, and whose symptoms are inadequately controlled with medium to high dose inhaled corticosteroids. Omalizumab has been shown to decrease the incidence of asthma exacerbations and improve asthma control in these patients. Dosing is based on the patient’s weight and serum IgE level and is given subcutaneously every 2–4 weeks. The FDA has ordered a black box warning to the label because of new reports of serious and life-threatening anaphylactic reactions (bronchospasm, hypotension, syncope, urticaria, and angioedema of the throat or tongue) in patients after treatment with omalizumab (Xolair). Based on reports from approximately 39,500 patients, anaphylaxis following omalizumab treatment occurred in at least 0.1% of treated people. Although these reactions occurred within 2 hours of receiving a omalizumab subcutaneous injection, they also included reports of serious delayed reactions 2–24 hours or even longer after receiving the injections. Anaphylaxis occurred after any dose of omalizumab (including the first dose), even in patients with no allergic reaction to previous doses. Omalizumab-treated patients should be observed in the facility for an extended period after the drug is given, and medical providers who administer the injection should be prepared to manage life-threatening anaphylactic reactions. Patients who receive omalizumab should be fully informed about the signs and symptoms of anaphylaxis, their chance of developing delayed anaphylaxis following each injection, and how to treat it, including the use of autoinjectable epinephrine. The small risks of malignant neoplasms (a variety of types, e.g., breast, nonmelanoma skin, prostate, melanoma, and parotid) in clinical studies of adults and adolescents (≥12 years of age) with asthma and other allergic disorders were reported in 20 of 4127 (0.5%) omalizumab-treated patients compared to 5 of 2236 (0.2%) controls.

Immunotherapy (discussed in more detail in a subsequent section) can be considered for children 5 years and older with allergic asthma who require steps 2, 3, and 4 therapy.

Continual monitoring is necessary to ensure that control of asthma is achieved and sustained. Once control is established, gradual reduction in therapy is appropriate and may help determine the minimum amount of medication necessary to maintain control. Regular follow-up visits with the clinician are important to assess the degree of control and consider appropriate adjustments in therapy. At each step, patients should be instructed to avoid or control exposure to allergens, irritants, or other factors that contribute to asthma severity.

Referral to an asthma specialist for consultation or co-management is recommended if there are difficulties
in achieving or maintaining control. For children younger than age 5 years, referral is recommended for moderate persistent asthma or if the patient requires step 3 or 4 care and should be considered if the patient requires step 2 care. For children 5 years and older, consultation with a specialist is recommended if the patient requires step 4 care or higher and should be considered at step 3. Referral is also recommended if allergen immunotherapy or anti-IgE therapy is being considered.

3. Exercise-induced bronchospasm—Exercise-induced bronchospasm should be anticipated in all asthma patients. It typically occurs during or minutes after vigorous activity, reaches its peak 5–10 minutes after stopping the activity, and usually resolves over the next 20–30 minutes. Participation in physical activity should be encouraged in children with asthma, although the choice of activity may need to be modified based on the severity of illness, presence of other triggers such as cold air, and, rarely, confounding factors such as osteoporosis. Poor endurance or exercise-induced bronchospasm can be an indication of poorly controlled persistent asthma. If symptoms occur during usual play activities, either initiation of or a step-up in long-term therapy is warranted. However, for those with exercise-induced bronchospasm as the only manifestation of asthma despite otherwise being “well-controlled,” treatment immediately prior to vigorous activity or exercise is usually effective. SABAs, leukotriene receptor antagonists, cromolyn, or nedocromil can be used before exercise. The combination of a SABA with either cromolyn or nedocromil is more effective than either drug alone. Salmeterol and formoterol may block exercise-induced bronchospasm for up to 12 hours (as discussed earlier). However, decreased duration of protection against exercise-induced bronchospasm can be expected with regular use. Montelukast may be effective up to 24 hours. An extended warm-up period may induce a refractory state, allowing patients to exercise without a need for repeat medications.

B. Acute Asthma

1. General measures—The most effective strategy in managing asthma exacerbations involves early recognition of warning signs and early treatment. For patients with moderate or severe persistent asthma or a history of severe exacerbations, this should include a written action plan. The latter usually defines the patient’s green, yellow, and red zones based on symptoms (and PEFR for patients with poor symptom perception) with corresponding measures to take according to the state the patient is in. PEFR cut-off values are conventionally set as > 80% (green), 50%–80% (yellow), and < 50% (red) of the child’s personal best. Prompt communication with the clinician is indicated with severe symptoms or a drop in peak flow or with decreased response to SABAs. At such times, intensification of therapy may include a short course of oral corticosteroids. The child should be removed from exposure to any irritants or allergens that could be contributing to the exacerbation.

2. Management at home—Early treatment of asthma exacerbations may prevent hospitalization and a life-threatening event. Initial treatment should be with a SABA such as albuterol or levalbuterol; 2–6 puffs from an MDI can be given every 20 minutes up to three times, or a single treatment can be given by nebulizer (0.05 mg/kg [minimum dose, 1.25 mg; maximum, 2.5 mg]) of 0.5% solution of albuterol in 2–3 mL saline; or 0.075 mg/kg [minimum dose, 1.25 mg; maximum, 5 mg] of levalbuterol. If the response is good as assessed by sustained symptom relief or improvement in PEFR to over 80% of the patient’s best, the SABA can be continued every 3–4 hours for 24–48 hours. Patients should be advised to seek medical care once excessive doses of bronchodilator therapy are used or for prolonged periods (eg, > 12 puffs/d for > 24 hours). Doubling the dose of inhaled corticosteroids is not proven sufficient to prevent worsening of exacerbations; however, recent evidence indicates that quadrupling the inhaled corticosteroid dose at the early sign of deterioration might be effective. If the patient does not completely improve from the initial therapy or PEFR falls between 50% and 80% predicted or personal best, the SABA should be continued, an oral corticosteroid should be added, and the patient should contact the physician urgently. If the child experiences marked distress or if PEFR persists at 50% or less, the patient should repeat the SABA immediately and go to the emergency department or call 911 or another emergency number for assistance.

3. Management in the office or emergency department—Functional assessment of the patient includes obtaining objective measures of airflow limitation with PEFR or FEV1 and monitoring the patient’s response to treatment; however, very severe exacerbations and respiratory distress may prevent the execution of lung function measurements using maximal expiratory maneuver. Flow-volume loops should be obtained to differentiate upper and lower airway obstruction, especially in patients with atypical presentation. Other tests may include oxygen saturation and blood gases. Chest radiographs are not recommended routinely but should be considered to rule out pneumothorax, pneumomediastinum, pneumonia, or lobar atelectasis. If the initial FEV1 or PEFR is over 40%, initial treatment can be with a SABA by inhaler (albuterol, 4–8 puffs) or nebulizer (0.15 mg/kg of albuterol 0.5% solution; minimum dose, 2.5 mg), up to three doses in the first hour. Oxygen should be given to maintain oxygen saturation at greater than 90%. Oral corticosteroids (1–2 mg/kg/d in divided doses; maximum of 60 mg/d for children aged ≤ 12 years and 80 mg/d for those > 12 years) should be instituted if the patient responds poorly to therapy if the patient has recently been on oral corticosteroids. Sensitivity to adrenergic drugs may improve after initiation of corticosteroids. For severe exacerbations or if the initial FEV1 or PEFR is under 40%, initial treatment should be with a high-dose SABA plus ipratropium bromide, 1.5–3 mL every 20 minutes for 3 doses (each 3 mL vial contains 0.5 mg ipratropium bromide and 2.5 mg albuterol), then as
needed by nebulizer. Continuous albuterol nebulized treatments (0.5 mg/kg/hour for small and 10–15 mg/hour for older children) can be administered for evidence of persistent obstruction. Oxygen should be given to maintain oxygen saturation at greater than 90%, and systemic corticosteroids should be administered. For patients with severe exacerbation having no response to initial aerosolized therapy, or for those who cannot cooperate with or who resist inhalation therapy, adjunctive therapies such as intravenous magnesium sulfate (25–75 mg/kg up to 2 g in children) and heliox-driven albuterol nebulization should be considered. Epinephrine 1:1000 or terbutaline 1 mg/mL (both 0.01 mg/kg up to 0.3–0.5 mg) may be administered subcutaneously every 20 minutes for three doses; although the use of intravenous β₂-agonists is still unproven. For impending or ongoing respiratory arrest, patients should be intubated and ventilated with 100% oxygen, given intravenous corticosteroids, and admitted to an intensive care unit (ICU). Potential indications for ICU admission also include any FEV₁ or PEFR less than 25% of predicted that improves less than 10% after treatment or values that fluctuate widely. (See Asthma [life-threatening] in Chapter 14.) Further treatment is based on clinical response and objective laboratory findings. Hospitalization should be considered strongly for any patient with a history of respiratory failure.

4. Hospital management—For patients who do not respond to outpatient and emergency department treatment, admission to the hospital becomes necessary for more aggressive care and support. The decision to hospitalize should also be based on presence of risk factors for mortality from asthma, duration and severity of symptoms, severity of airflow limitation, course and severity of previous exacerbations, medication use at the time of the exacerbation, access to medical care, and home and psychosocial conditions. Fluids should be given at maintenance requirements unless the patient has poor oral intake secondary to respiratory distress or vomiting, because overhydration may contribute to pulmonary edema associated with high intrapleural pressures generated in severe asthma. Potassium requirements should be kept in mind because both corticosteroids and β₂-agonists can cause potassium loss. Moisturized oxygen should be titrated by oximetry to maintain oxygen saturation above 90%. Inhaled β₂-agonist should be continued by nebulization in single doses as needed or by continuous therapy, along with systemic corticosteroids (as discussed earlier). Ipratropium is no longer recommended during hospitalization. In addition, the role of methylxanthines in hospitalized children remains controversial. Antibiotics may be necessary to treat coexisting bacterial infection. Sedatives and anxiolytic agents are contraindicated in severely ill patients owing to their depressive effects on respiration. Chest physiotherapy is usually not recommended for acute exacerbations.

5. Patient discharge—Criteria for discharging patients home from the office or emergency department should include a sustained response of at least 1 hour to bronchodilator therapy with FEV₁ or PEFR greater than 70% of predicted or personal best and oxygen saturation greater than 90% in room air. Prior to discharge, the patient’s or caregiver’s ability to continue therapy and assess symptoms appropriately needs to be considered. Patients should be given an action plan for management of recurrent symptoms or exacerbations, and instructions about medications should be reviewed. The inhaled SABA and oral corticosteroids should be continued, the latter for 3–10 days. Finally, the patient or caregiver should be instructed about the follow-up visit, typically within 1 week. Hospitalized patients should receive more intensive education prior to discharge. Referral to an asthma specialist should be considered for all children with severe exacerbations or multiple emergency department visits or hospitalizations.

Prognosis

Since the 1970s, morbidity rates for asthma have increased, but mortality rates may have stabilized. Mortality statistics indicate that a high percentage of deaths have resulted from underrecognition of asthma severity and undertreatment, particularly in labile asthmatic patients and in asthmatic patients whose perception of pulmonary obstruction is poor. Long-term outcome studies suggest that children with mild symptoms generally outgrow their asthma, while patients with more severe symptoms, marked airway hyperresponsiveness, and a greater degree of atopy tend to have persistent disease. Data from an unselected birth cohort from New Zealand showed more than one in four children had wheezing that persisted from childhood to adulthood or that relapsed after remission. Recent evidence suggests that early intervention with anti-inflammatory therapy does not alter the development of persistent asthma, and it is also unclear if such intervention or environmental control measures influence the natural history of childhood asthma. Nonetheless, the pediatrician or primary care provider together with the asthma specialist has the responsibility to optimize control and, it is hoped, reduce the severity of asthma in children. Interventions that can have long-term effects such as halting progression or inducing remission are necessary to decrease the public health burden of this common condition.

ALLERGIC RHINOCONJUNCTIVITIS

General Considerations

Allergic rhinoconjunctivitis is the most common allergic disease and significantly affects quality of life as well as school performance and attendance. It frequently coexists with asthma, can impact asthma control, and is a risk factor for subsequent development of asthma. Over 80% of patients with asthma have rhinitis and 10%–14% of patients with rhinitis have asthma. About 80% of individuals with allergic rhinitis develop their symptoms before age 20 years. It is estimated that 13% of children have a physician diagnosis of allergic rhinitis. Prevalence of this disease increases during childhood, peaking at 15% in the postadolescent years. Although allergic rhinoconjunctivitis is more common in boys during early childhood, there is little difference in incidence between the sexes after adolescence. Race and socioeconomic status are not considered to be important factors.

The pathologic changes in allergic rhinoconjunctivitis are chiefly hyperemia, edema, and increased serous and mucoid secretions caused by mediator release, all of which lead to variable degrees of nasal obstruction and conjunctival injection, nasal and ocular pruritus, or nasal and ocular discharge. Ocular allergies can occur in isolation, but more commonly, they are in conjunction with nasal symptoms. This process may involve other structures, including the sinuses and possibly the middle ear. Inhalant allergens are primarily responsible for symptoms, but food allergens can cause symptoms as well. Children with allergic rhinitis seem to be more susceptible to—or at least may experience more symptoms from—upper respiratory infections, which, in turn, may aggravate the allergic rhinitis.

Allergic rhinoconjunctivitis has been classified as perennial, seasonal (hay fever), or episodic; however, there are areas where pollens and soil molds may be present year round while exposure to typical perennial allergens such as indoor furred animals may be intermittent. For this reason, the preferred terms are intermittent (ie, symptoms present < 4 days a week or for < 4 weeks) and persistent (ie, symptoms present > 4 days a week and for > 4 weeks). In addition, severity should be noted as mild (ie, without impairment or disturbance of sleep, daily activities, leisure, sport, school, or work, or without troublesome symptoms) or moderate-severe (ie, presence of one or more of the aforementioned). The major pollen groups in the temperate zones include trees (late winter to early spring), grasses (late spring to early summer), and weeds (late summer to early fall), but seasons can vary significantly in different parts of the country. Mold spores also cause seasonal allergic rhinitis, principally in the summer and fall. Seasonal allergy symptoms may be aggravated by coincident exposure to perennial allergens.

Clinical Findings

A. Symptoms and Signs

Patients may complain of itching of the nose, eyes, palate, or pharynx and loss of smell or taste. Nasal itching can cause paroxysmal sneezing and epistaxis. Repeated rubbing of the nose (so-called allergic salute) may lead to a horizontal crease across the lower third of the nose. Nasal obstruction is associated with mouth breathing, nasal speech, allergic salute, and snoring. Nasal turbinates may appear pale blue and swollen with dimpling or injected with minimal edema. Typically, clear and thin nasal secretions are increased, with anterior rhinorrhea, sniffing, postnasal drip, and congested cough. Nasal secretions often cause poor appetite, fatigue,
and pharyngeal irritation. Conjunctival injection, tearing, periorbital edema, and infraorbital cyanosis (so-called allergic shiners) are frequently observed. Increased pharyngeal lymphoid tissue (“cobblestoning”) from chronic drainage and enlarged tonsillar and adenoidal tissue may be present.

B. Laboratory Findings

Eosinophilia often can be demonstrated on smears of nasal secretions or blood. This is a frequent but nonspecific finding and may occur in nonallergic conditions. Although serum IgE may be elevated, measurement of total IgE is a poor screening tool owing to the wide overlap between atopic and nonatopic subjects. Skin testing to identify allergen-specific IgE is the most sensitive and specific test for inhalant allergies; alternatively, the Phadia ImmunoCAP assay, radioallergosorbent test (RAST), or other in vitro tests can be done for suspected allergens.

Differential Diagnosis

Disorders that need to be differentiated from allergic rhinitis include infectious rhinosinusitis. Foreign bodies and structural abnormalities such as choanal atresia, marked septal deviation, nasal polyps, and adenoideal hypertrophy may cause chronic symptoms. Overuse of topical nasal decongestants may result in rhinitis medicamentosa (rebound congestion). Use of medications such as propranolol, clonidine, and some psychoactive drugs may cause nasal congestion. Illicit drugs such as cocaine can cause rhinorrhea. Spicy or hot foods may cause gustatory rhinitis. Nonallergic rhinitis with eosinophilia syndrome is usually not seen in young children. Vasomotor rhinitis is associated with persistent symptoms but without allergic exposure. Less common causes of symptoms that may be confused with allergic rhinitis include pregnancy, congenital syphilis, hypothyroidism, tumors, and cerebrospinal fluid rhinorrhea.

As in the differential diagnoses for allergic rhinitis, infectious conjunctivitis (secondary to viral, bacterial, or chlamydial etiology) can mimic allergic eye disorders. In this case, it typically develops in one eye first, and symptoms include stinging or burning sensation (rather than pruritus) with a foreign body sensation and eye discharge (watery, mucoid, or purulent). Nasolacrimal duct obstruction, foreign body, blepharoconjunctivitis, dry eye, uveitis, and trauma are other masqueraders of ocular allergy.

The other conditions which comprise allergic eye diseases, presenting with bilateral conjunctivitis, include atopic keratoconjunctivitis, vernal conjunctivitis, and giant papillary conjunctivitis. Except for giant papillary conjunctivitis, the three (allergic conjunctivitis, atopic keratoconjunctivitis, and vernal conjunctivitis) are associated with allergic sensitization. Atopic keratoconjunctivitis and vernal conjunctivitis are both vision-threatening. Atopic keratoconjunctivitis is rarely seen before late adolescence and it most commonly involves the lower tarsal conjunctiva. Ocular symptoms (itching, burning, and tearing) are more severe than in allergic conjunctivitis and persist all year round, with accompanying eyelid eczema with erythema and thick, dry scaling skin, which can extend to the periorbital skin and cheeks. Vernal conjunctivitis is characterized by giant papillae, described as cobblestoning, seen in the upper tarsal conjunctiva. It affects boys more often than girls and patients of Asian and African descent are more predisposed. It affects individuals in temperate areas, with exacerbations in the spring and summer months. In addition to severe pruritus which can be exacerbated by exposure to irritants, light, or perspiration, other accompanying signs and symptoms include photophobia, foreign body sensation, lacrimation, and presence of stringy or thick, ropey discharge, transient yellow-white points in the limbus (Trantas dots) and conjunctiva (Horner points), corneal “shield” ulcers, Dennie lines (prominent skin folds that extend in an arc form from the inner canthus beneath and parallel to the lower lid margin), and prominently long eyelashes. Giant papillary conjunctivitis is associated with exposure to foreign bodies such as contact lenses, ocular prostheses, and sutures. It is characterized by mild ocular itching, tearing, and mucoid discharge especially on awakening. Trantas dots, limbal infiltration, bulbar injection, and edema may also be found. One eye condition, contact allergy, which can also involve the conjunctivae especially when associated with use of topical medications, contact lens solutions, and preservatives, typically affects the eyelids.

Complications

Sinusitis may accompany allergic rhinitis. Allergic mucosal swelling of the sinus ostia can obstruct sinus drainage, interfering with normal sinus function and predisposing to chronic mucosal disease. Nasal polyps due to allergy are unusual in children, and cystic fibrosis should be considered if they are present. Unlike vision-threatening complications associated with atopic keratoconjunctivitis and vernal conjunctivitis, allergic conjunctivitis manifests primarily with significant pruritus and discomfort affecting the patients’ quality of life.

Treatment

A. General Measures

The value of identification and avoidance of causative allergens cannot be overstated. Reducing indoor allergens through environmental control measures as discussed in the section on asthma can be very effective. Nasal saline irrigation may be useful. For ocular allergies, cold compresses and lubrication are also important.

B. Pharmacologic Therapy

Evidence-based clinical practice guidelines such as the Allergic Rhinitis and its Impact on Asthma (ARIA) which include the
pharmacologic management of allergic rhinitis have been developed based on the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach. While ARIA recommends the use of intranasal corticosteroids for adults with allergic rhinitis, the use of the topical corticosteroids over oral antihistamines for children is suggested.

The treatment of mild intermittent rhinitis includes oral or intranasal H₁ antihistamines and intranasal decongestants (for < 10 days and not to be repeated more than twice a month). Oral decongestants are not usually recommended in children. Options for moderate-severe intermittent rhinitis are oral or intranasal antihistamines, oral H₁ antihistamines and decongestants, intranasal corticosteroids, and cromones. The same medication options are available for persistent rhinitis, but a stepwise approach is proposed both for treatment of mild and moderate-severe persistent rhinitis. For mild persistent rhinitis, reassessment after 2–4 weeks is recommended and treatment should be continued, with a possible reduction in intranasal corticosteroids, even if the symptoms have abated. If, however, the patient has persistent mild symptoms while on H₁ antihistamines or cromones, an intranasal corticosteroid is appropriate. For moderate-severe persistent disease, use of intranasal corticosteroids as first-line therapy is recommended. For severe nasal congestion, either a short 1- to 2-week course of an oral corticosteroid or an intranasal decongestant for less than 10 days may be added. If the patient improves, the treatment should last for at least 3 months or until the pollen season is over. If the patient does not improve within 2–4 weeks despite adequate compliance and use of medications, comorbidities such as nasal polyps, sinusitis, and significant allergen exposure should be considered, as well as the possibility of misdiagnosis. Once these are ruled out, options include increasing the dose of the intranasal corticosteroid, combination therapy with an H₁ antihistamine (particularly if major symptoms are sneezing, itching, or rhinorrhea), ipratropium bromide (if major symptom is rhinorrhea), or an oral H₁ antihistamine and decongestant. Referral to a specialist may be considered if the treatment is not sufficient.

For allergic rhinoconjunctivitis, topical nasal corticosteroids also reduce ocular symptoms, presumably through a naso-ocular reflex. For ocular allergies which persist or occur independent of rhinitis, pharmacologic treatment includes use of oral or topical antihistamines, topical decongestants, mast cell stabilizers, and anti-inflammatory agents. In general, topical ophthalmic drops should not be used with contact lenses. Topical decongestants relieve erythema, congestion, and edema but do not affect the allergic response. Combined therapy with an antihistamine and a vasoconstrictive agent is more effective than either agent alone. Topical medications with both antihistamine and mast cell blocking properties provide the most benefits which incorporate fast-acting symptom relief and anti-inflammatory action. Refrigerating ophthalmic drops before use can provide soothing relief as well. However, children can get wary of eye drops and prefer oral preparations. Avoiding contamination by preventing the applicator tip from touching the eye or eyelid is important. Severe ocular allergy can be treated with topical, or rarely, oral corticosteroids. In such a case, a referral to an ophthalmologist is warranted, as these treatments can be associated with elevation of the intraocular pressure, viral infections, and cataract formation.

Allergen immunotherapy can be very effective in allergic rhinoconjunctivitis and may decrease the requirement for medications to control the symptoms in the long term.

1. **Antihistamines**—Antihistamines help control itching, sneezing, and rhinorrhea. Sedating antihistamines include diphenhydramine, chlorpheniramine, hydroxyzine, and clemastine. Sedating antihistamines may cause daytime somnolence and negatively affect school performance and other activities, especially during. Second-generation antihistamines include loratadine, desloratadine, cetirizine, and fexofenadine. Cetirizine is approved for use in children aged 6–23 months (2.5 mg daily), 2–5 years (2.5–50 mg/d or 2.5 mg twice a day), and 6 years or older (5–10 mg/d).

   It is now available without a prescription. Loratadine is approved for use in children aged 2–5 years (5 mg/d) and 6 years or older (10 mg/d), and is available without prescription in tablet, rapidly disintegrating tablet, and liquid formulations. Desloratadine is approved for use in children aged 6–11 months (1 mg/d), 1–5 years (1.25 mg/d), and for 12 years and older (5 mg/d). Fexofenadine is approved for children aged 6–23 months (15 mg twice a day), 2–11 years (30 mg twice a day), and 12 years or older (60 mg twice a day or 180 mg once daily), and is also now available without a prescription. Levocetirizine (5 mg/d) is approved for children aged 6 years and older. Loratadine, fexofenadine, and cetirizine are available in combination with pseudoephedrine for patients aged 12 years or older, although regular use of these combination products is not recommended. Azelastine is available in nasal and ophthalmic formulations. Levocabastine and emedastine are available as ophthalmic preparations. They should not be used for treatment of contact lens–related irritation and caution should be implemented with concomitant use of soft contact lenses.

2. **Mast cell stabilizers**—Intranasal ipratropium can be used as adjunctive therapy for rhinorrhea. Intranasal cromolyn may be used alone or in conjunction with oral antihistamines and decongestants. It is most effective when used prophylactically, one to two sprays/nostril, four times a day. This dose may be tapered if symptom control is achieved. Rarely, patients complain of nasal irritation or burning. Most patients find complying with four-times-daily dosing difficult. Cromolyn is also available in an ophthalmic solution (see also Chapter 16). It can be used to treat giant papillary and vernal conjunctivitis. Other ophthalmic mast cell...
stabilizers include lodoxamide 0.1% solution (can be used for vernal keratoconjunctivitis as well), one to two drops four times a day; nedocromil sodium 2%, one to two drops two times a day; and pemirolast potassium 0.1%, one to two drops four times a day.

### 3. Decongestants and Vasoconstrictor Agents
Nasal α-adrenergic agents help to relieve nasal congestion and ophthalmic vasoconstrictors relieve ocular erythema, edema, and congestion. Topical nasal decongestants such as phenylephrine and oxymetazoline should not be used for more than 4 days for severe episodes because prolonged use may be associated with rhinitis medicamentosa. As with nasal decongestants, a rebound phenomenon (ie, conjunctivitis medicamentosa with hyperemia and stinging/burning) can occur with chronic use of ophthalmic vasoconstrictive agents such as naphazoline and tetrahydrozoline. Oral decongestants, including pseudoephedrine, phenylephrine, and phenylpropanolamine, are often combined with antihistamines or expectorants and cough suppressants in over-the-counter (OTC) cold medications, but there are no convincing data to support the use of decongestants for upper respiratory illnesses in children nor for regular use in patients with allergic rhinitis. They may cause insomnia, agitation, tachycardia, and, rarely, cardiac arrhythmias. Of note, the FDA has recommended the removal of phenylpropanolamine from all drug products due to a public health advisory concerning the risk of hemorrhagic stroke associated with its use.

### 4. Corticosteroids
Intranasal corticosteroid sprays are effective in controlling allergic rhinitis if used chronically. They are minimally absorbed in usual doses and are available in pressurized nasal inhalers and aqueous sprays. Mometasone and fluticasone furoate nasal sprays have been approved for use in children as young as age 2 years (one spray in each nostril once daily) and in children 12 years or older (two sprays/nostril once daily). Fluticasone propionate nasal spray is approved for children 4 years or older, and budesonide and triamcinolone nasal sprays are approved for those 6 years or older (one to two sprays/nostril once daily). Flunisolide is approved for ages 6–14 years (one spray/nostril three times a day or two sprays/nostril twice a day). Ciclesonide is approved for seasonal allergic rhinitis in children 6 years and older and those with perennial allergic rhinitis for children 12 years and older, two sprays in each nostril once daily. Side effects include nasal irritation, soreness, and bleeding, although epistaxis occurs commonly in patients with allergic rhinitis if corticosteroids are used chronically. Rarely, these drugs can cause septal perforation. Excessive doses may produce systemic effects, especially if used together with orally inhaled steroids for asthma. Onset of action is within hours, although clinical benefit is usually not observed for a week or more. They may be effective alone or together with antihistamines.

Use of oral or topical (eg, loteprednol etabonate) corticosteroids for the treatment of ocular allergy should be worked out in conjunction with an ophthalmologist due to potential complications mentioned in the preceding section.

### 5. Other Pharmacologic Agents
Montelukast is approved for perennial allergic rhinitis in children aged 6 months and older (4 mg/d for ages 6–23 months) and seasonal allergic rhinitis in children 2 years and older in doses as discussed in the preceding section on Pharmacologic Therapy under Treatment, Chronic Asthma. Oral antihistamines are also available in combination with a decongestant. Ketorolac, a nonsteroidal anti-inflammatory drug (NSAID), is available as an ophthalmic solution but should be avoided in patients with aspirin or NSAID sensitivity and should be used with caution in those with complicated eye surgeries, corneal denervation or epithelial defects, ocular surface diseases, diabetes mellitus, or rheumatoid arthritis. Combination ophthalmic preparations are available. Both antazoline and pheniramine are antihistamine/vasoconstrictor formulations. Olopatadine 0.1%, epinastine 0.05%, and ketotifen 0.025% ophthalmic solutions have antihistamine and mast cell–stabilizing actions and can be given to children older than age 3 years as one drop twice a day (8 hours apart) for olopatadine and every 8–12 hours for ketotifen, respectively. Ketotifen fumarate 0.025% is now available as an OTC ophthalmic medication. Olopatadine 0.2% is the first once-daily ophthalmic medication available for the treatment of ocular pruritus associated with allergic conjunctivitis.

### C. Surgical Therapy
Surgical procedures, including turbinectomy, polypectomy, and functional endoscopic sinus surgery, are rarely indicated in allergic rhinitis or chronic hyperplastic sinusitis.

### D. Immunotherapy
Allergen immunotherapy should be considered when symptoms are severe and due to unavoidable exposure to inhalant allergens, especially if symptomatic measures have failed. Immunotherapy is the only form of therapy that may alter the course of the disease. It should not be prescribed by sending the patient’s serum to a laboratory where extracts based on in vitro tests are prepared for the patient (ie, the remote practice of allergy). Subcutaneous immunotherapy should be done in a facility where a physician prepared to treat anaphylaxis is present. Patients with concomitant asthma should not receive an injection if their asthma is not under good control (ie, peak flows preinjection are below 80% of personal best), and the patient should wait for 25–30 minutes after an injection before leaving the facility. Outcomes with single allergen immunotherapy show success rates of approximately 80%. The optimal duration of therapy is unknown, but data suggest that immunotherapy
for 3–5 years may have lasting benefit. Sublingual immunotherapy has been developed and recommended in Europe, Argentina, Brazil, the Gulf States, and South Africa, for treatment of allergic rhinitis caused by pollens in both adults and children, and for allergic rhinitis caused by dust mites only in adults. Although local adverse effects are common (in about 35%), this form of immunotherapy allows for a less stringent administration as this can be given at home. This is still considered experimental in the United States, as extracts have not been FDA-approved.

**Prognosis**

Allergic rhinoconjunctivitis associated with sensitization to indoor allergens tends to be protracted unless specific allergens can be identified and eliminated from the environment. In seasonal allergic rhinoconjunctivitis, symptoms are usually most severe from adolescence through mid-adult life. After moving to a region devoid of problem allergens, patients may be symptom-free for several years, but they can develop new sensitivities to local Aeroallergens.

**Clinical Findings**

**A. Symptoms and Signs**

Atopic dermatitis has no pathognomonic skin lesions or laboratory parameters. Diagnosis is based on the clinical features, including severe pruritus, a chronically relapsing course, and typical morphology and distribution of the skin lesions. Acute atopic dermatitis is characterized by intensely pruritic, erythematous papules associated with excoriations, vesiculations, and serous exudate; subacute atopic dermatitis by erythematous, excoriated, scaling papules; and chronic atopic dermatitis by thickened skin with accentuated markings (lichenification) and fibrotic papules. Patients with chronic atopic dermatitis may have all three types of lesions present concurrently. Patients usually have dry, “lackluster” skin. During infancy, atopic dermatitis involves primarily the face, scalp, and extensor surfaces of the extremities. The diaper area is usually spared. When involved, it may be secondarily infected with *Candida*. In older patients with longstanding disease, the flexural folds of the extremities are the predominant location of lesions.

**B. Laboratory Findings**

Identification of allergens involves taking a careful history and performing selective immediate hypersensitivity skin tests or in vitro tests when appropriate. Negative skin tests with proper controls have a high predictive value for ruling out a suspected allergen. Positive skin tests have a lower correlation with clinical symptoms in suspected food allergen–induced atopic dermatitis and should be confirmed with double-blind, placebo-controlled food challenges unless there is a coincidental history of anaphylaxis to the suspected food. Alternatively, specific IgE levels to milk, egg, peanut, and fish proteins have been established with the Phadia ImmunoCAP assay correlating with a greater than 95% chance of a clinical reaction.

Elevated serum IgE levels can be demonstrated in 80%–85% of patients with atopic dermatitis, and a similar number have positive immediate skin tests or in vitro tests with food and inhalant allergens. Several well-controlled studies suggest that specific allergens can influence the course of this disease. However, triggers for clinical disease cannot be predicted simply by performing allergy testing. Double-blind, placebo-controlled food challenges show that food allergens can cause exacerbations in a subset of patients with atopic dermatitis. Although lesions induced by single positive challenges are usually transient, repeated challenges, more typical of real-life exposure, can result in eczematous lesions. Furthermore, elimination of food allergens results in amelioration of skin disease and a decrease in spontaneous basophil histamine release. Exacerbation of atopic dermatitis can occur with exposure to Aeroallergens such as house dust mites, and environmental control measures have been
shown to result in clinical improvement. Patients can make specific IgE directed at *Staphylococcus aureus* toxins secreted on the skin, and this correlates with clinical severity better than total serum IgE levels. Eosinophilia may occur. Routine skin biopsy does not differentiate atopic dermatitis from other eczematous processes but may be helpful in atypical cases. Tests for the most common filaggrin gene mutations using DNA from buccal swabs or blood are available. Testing may identify patients who would be at increased risk for more severe, persistent atopic dermatitis and be more likely to develop allergic sensitizations and asthma.

### Differential Diagnosis

Scabies can present as a pruritic skin disease. However, distribution in the genital and axillary areas and the presence of linear lesions as well as skin scrapings may help to distinguish it from atopic dermatitis. Seborrheic dermatitis may be distinguished by a lack of significant pruritus; its predilection for the scalp (so-called cradle cap); and its coarse, yellowish scales. Allergic contact dermatitis may be suggested by the distribution of lesions with a greater demarcation of dermatitis than in atopic dermatitis. Occasionally, allergic contact dermatitis superimposed on atopic dermatitis may appear as an acute flare of the underlying disease. Nummular eczema is characterized by coin-shaped plaques. Although unusual in children, mycosis fungoides or cutaneous T-cell lymphoma has been described and is diagnosed by skin biopsy. Eczematous rash has been reported in patients with human immunodeficiency virus (HIV) infection. Other disorders that may resemble atopic dermatitis include Wiskott-Aldrich syndrome, severe combined immunodeficiency disease, hyper-IgE syndrome, immunodeficiency with DOCK8 mutations, IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked) syndrome, zinc deficiency, phenylketonuria, and Letterer-Siwe disease.

### Complications

Ocular complications associated with atopic dermatitis can lead to significant morbidity. Atopic keratoconjunctivitis is always bilateral, and symptoms include itching, burning, tearing, and copious mucoid discharge. It is frequently associated with eyelid dermatitis and chronic blepharitis, and may result in visual impairment from corneal scarring (see Chapter 16). Keratoconus in atopic dermatitis is believed to result from persistent rubbing of the eyes in patients with atopic dermatitis and allergic rhinitis. Anterior subcapsular cataracts may develop during adolescence or early adult life.

Patients with atopic dermatitis have increased susceptibility to infection or colonization with a variety of organisms. These include viral infections with herpes simplex, molluscum contagiosum, and human papillomavirus. Of note, even a past history of atopic dermatitis is considered a contraindication for receiving the current smallpox (vaccinia) vaccine. Superimposed dermatophytosis may cause atopic dermatitis to flare. *S. aureus* can be cultured from the skin of more than 90% of patients with atopic dermatitis, compared with only 5% of normal subjects. Patients with atopic dermatitis often have toxin-secreting *S. aureus* cultured from their skin and can make specific IgE antibodies against the toxins found on their skin. *S. aureus* toxins can act as superantigens, contributing to persistent inflammation or exacerbations of atopic dermatitis. Patients without obvious superinfection may show a better response to combined antistaphylococcal and topical corticosteroid therapy than to corticosteroids alone. Although recurrent staphylococcal pustulosis can be a significant problem in atopic dermatitis, invasive *S. aureus* infections occur rarely and should raise the possibility of an immunodeficiency such as hyper-IgE syndrome. Patients with atopic dermatitis may be predisposed to colonization and infections by microbial organisms due to decreased synthesis of antimicrobial peptides in the skin, which may be mediated by increased levels of TH2-type cytokines.

Patients with atopic dermatitis often have a nonspecific hand dermatitis. This is frequently irritant in nature and aggravated by repeated wetting.

Nutritional disturbances may result from unwarranted and unnecessarily vigorous dietary restrictions imposed by physicians and parents.

Poor academic performance and behavioral disturbances may be a result of uncontrolled intense or frequent itching, sleep loss, and poor self-image. Severe disease may lead to problems with social interactions and self-esteem.

### Treatment

#### A. General Measures

Patients with atopic dermatitis have a lowered threshold of irritant responsiveness. Avoidance of irritants such as detergents, chemicals, and abrasive materials as well as extremes of temperature and humidity is important in managing this disease. New clothing should be washed to reduce the content of formaldehyde and other chemicals. Because residual laundry detergent in clothing may be irritating, using a liquid rather than a powder detergent and adding an extra rinse cycle is beneficial. Occlusive clothing should be avoided in favor of cotton or cotton blends. Temperature in the home and work environments should be controlled to minimize sweating. Swimming is usually well tolerated; however, because swimming pools are treated with chlorine or bromine, patients should shower and use a mild cleanser to remove these chemicals, then apply a moisturizer or occlusive agent. Sunlight may be beneficial to some patients with atopic dermatitis, but nonsensitizing sunscreens should be used to avoid sunburn. Prolonged sun exposure can cause evaporative losses, overheating, and sweating, all of which can be irritating.
In children who have undergone controlled food challenges, eggs, milk, peanuts, soy, wheat, and fish account for approximately 90% of the food allergens that exacerbate atopic dermatitis. Avoidance of foods implicated in controlled challenges can lead to clinical improvement. Extensive elimination diets, which can be nutritionally unsound and burdensome, are almost never warranted because even patients with multiple positive skin tests rarely react to more than three foods on blinded challenges.

In patients who demonstrate specific IgE to dust mite allergen, environmental control measures aimed at reducing the dust mite load improve atopic dermatitis. These include use of dust mite–proof covers on pillows and mattresses, washing linens weekly in hot water, decreasing indoor humidity levels, and in some cases removing bedroom carpeting.

Counseling may be of benefit when dealing with the frustrations associated with atopic dermatitis. Relaxation, behavioral modification, or biofeedback training may help patients with habitual scratching. Patients with severe or disfiguring disease may require psychotherapy.

Clinicians should provide the patient and family with both general information and specific written skin care recommendations. The patient or parent should demonstrate an appropriate level of understanding to help ensure a good outcome. Educational pamphlets and a video about atopic dermatitis can be obtained from the National Eczema Association, a national nonprofit, patient-oriented organization, at: (800) 818-7546; http://www.nationaleczema.org.

### B. Hydration

Patients with atopic dermatitis have evaporative losses due to a defective skin barrier, so soaking the affected area or bathing for 10–15 minutes in warm water, then applying an occlusive agent to retain the absorbed water, is an essential component of therapy. Oatmeal or baking soda added to the bath may feel soothing to certain patients but does not improve water absorption. Atopic dermatitis of the face or neck can be treated by applying a wet facecloth or towel to the involved area. The washcloth may be more readily accepted by a child if it is turned into a mask and also allows the older patient to remain functional. Lesions limited to the hands or feet can be treated by soaking in a basin. Daily baths may be needed and increased to several times daily during flares of atopic dermatitis, while showers may be adequate for patients with mild disease. It is important to use an occlusive preparation within a few minutes after soaking the skin to prevent evaporation, which is both drying and irritating.

### C. Moisturizers and Occlusives

An effective emollient combined with hydration therapy will help skin healing and can reduce the need for topical corticosteroids. Moisturizers are available as lotions, creams, and ointments. Because lotions contain more water than creams, they are more drying because of their evaporative effect. Preservatives and fragrances in lotions and creams may cause skin irritation. Moisturizers often need to be applied several times daily on a long-term basis and should be obtained in the largest size available. Crisco shortening can be substituted as an inexpensive alternative. Petroleum jelly (Vaseline) is an effective occlusive agent when used to seal in water after bathing. Topical nonsteroidal creams approved as medical devices (thus, currently requiring prescriptions) for relief and management of signs and symptoms of dermatoses include Atopiclair, MimiX, EpiCeram, and Eletone.

### D. Corticosteroids

Corticosteroids reduce the inflammation and pruritus in atopic dermatitis. Topical corticosteroids can decrease S aureus colonization. Systemic corticosteroids, including oral prednisone, should be avoided in the management of this chronic relapsing disease. The dramatic improvement observed with systemic corticosteroids may be associated with an equally dramatic flaring of atopic dermatitis following their discontinuation. Topical corticosteroids are available in a wide variety of formulations, ranging from extremely high-potency to low-potency preparations (see Table 15–3). Choice of a particular product depends on the severity and distribution of skin lesions. Patients need to be counseled regarding the potency of their corticosteroid preparation and its potential side effects. In general, the least potent agent that is effective should be used. However, choosing a preparation that is too weak may result in persistence or worsening of the atopic dermatitis. Side effects include thinning of the skin, telangiectasias, bruising, hypopigmentation, acne, and striae, although these occur infrequently when low- to medium-potency topical corticosteroids are used appropriately. In contrast, use of potent topical corticosteroids for prolonged periods—especially under occlusion—may result in significant atrophic changes as well as systemic side effects. The face (especially the eyelids) and intertriginous areas are especially sensitive to corticosteroid side effects, and only low-potency preparations should be used routinely on these areas. Because topical corticosteroids are commercially available in a variety of bases, including ointments, creams, lotions, solutions, gels, and sprays, there is no need to compound them. Ointments are most occlusive and in general provide better delivery of the medication while preventing evaporative losses. However, in a humid environment, creams may be better tolerated than ointments because the increased occlusion may cause itching or even folliculitis. Creams and lotions, while easier to spread, can contribute to skin dryness and irritation. Solutions can be used on the scalp and hirsute areas, although they can be irritating, especially to open lesions. With clinical improvement, a less potent corticosteroid should be prescribed and
the frequency of use decreased. Topical corticosteroids can be discontinued when inflammation resolves, but hydration and moisturizers need to be continued. Several topical steroids including fluticasone 0.05% cream and desonide 0.05% hydrogel have been approved in infants as young as 3 months of age for up to 28 days.

E. Topical Calcineurin Inhibitors

Tacrolimus and pimecrolimus are immunomodulatory agents that inhibit the transcription of proinflammatory cytokines as well as other allergic mediators and target key cells in allergic inflammation. They are available in topical formulations, and long-term studies have confirmed both efficacy and safety. Local burning at the site of application, which occurs more frequently with tacrolimus ointment, has been the most common side effect, although this is usually a transient problem. Tacrolimus ointment—0.03% for children 2–15 years of age and 0.1% for older patients—is approved for twice daily short-term and intermittent long-term use in moderate to severe atopic dermatitis. Pimecrolimus 1% cream is approved for patients 2 years of age or older who have mild to moderate atopic dermatitis. As a precaution, patients should wear sunscreen with both drugs. In Europe, tacrolimus ointment is approved as twice weekly maintenance therapy for patients 2 years and older with a relapsing course after clearing up eczema with reevaluation of need for continued therapy after 12 months.

Although there is no evidence of a causal link between cancer and the use of topical calcineurin inhibitors, the FDA has issued a boxed warning for pimecrolimus cream and tacrolimus ointment because of a lack of long-term safety data (see U.S. package inserts for Elidel [Novartis] and Protopic [Astellas]). The new labeling states that these drugs are recommended as second-line treatment for short-term and noncontinuous chronic treatment and that their use in children younger than the age of 2 years is currently not recommended.

F. Tar Preparations

Tar preparations are used primarily in shampoos and rarely as bath additives. Side effects associated with tar products include skin dryness or irritation, especially if applied to inflamed skin, and, less commonly, photosensitivity reactions and folliculitis.

G. Wet Dressings

Wet dressings are used together with hydration and topical corticosteroids for the treatment of severe atopic dermatitis. They can serve as an effective barrier against the persistent scratching that often undermines therapy. Total body dressings can be applied by using wet pajamas or long underwear with dry pajamas or a sweat suit on top. Hands and feet can be covered by wet tube socks with dry tube socks on top. Alternatively, wet gauze with a layer of dry gauze over it can be used and secured in place with an elastic bandage. Dressings can be removed when they dry out, usually after several hours, and are often best tolerated at bedtime. Incorrect use of wet dressings can result in chilling, maceration of the skin, or secondary infection.

H. Anti-Infective Therapy

Systemic antibiotic therapy may be important when treating atopic dermatitis secondarily infected with S. aureus. For limited areas of involvement, a topical antibiotic such as mupirocin or retapamulin ointment may be effective. A first- or second-generation cephalosporin or semisynthetic penicillin is usually the first choice for oral therapy, as erythromycin-resistant organisms are fairly common. Overuse may result in colonization by methicillin-resistant S. aureus. Bleach baths (6% sodium hypochlorite, ½ cup in a full tub of water) two times per week in combination with nasal mupirocin (twice daily for 5 consecutive days per month) may be helpful for patients with recurrent methicillin-resistant S. aureus, although some patients find this treatment irritating.

Disseminated eczema herpeticum usually requires treatment with systemic acyclovir. Patients with recurrent cutaneous herpetic lesions can be given prophylactic oral acyclovir. Superficial dermatophytosis and Malassezia sympodialis infection can be treated with topical or (rarely) systemic antifungal agents.

I. Antipruritic Agents

Pruritus is usually the least well-tolerated symptom of atopic dermatitis. Oral antihistamines and anxiolytics may be effective owing to their tranquilizing and sedating effects and can be taken mostly in the evening to avoid daytime somnolence. Nonsedating antihistamines may be less effective in treating pruritus, although beneficial effects have been reported in blinded studies. Use of topical antihistamines and local anesthetics should be avoided because of potential sensitization.

J. Recalcitrant Disease

Patients who are erythrodermic or who appear toxic may need to be hospitalized. Hospitalization may also be appropriate for those with severe disease who fail outpatient management. Marked clinical improvement often occurs when the patient is removed from environmental allergens or stressors. In the hospital, compliance with therapy can be monitored, the patient and family can receive intense education, and controlled provocative challenges can be conducted to help identify triggering factors.

Limited published data are available on use of cyclosporine in children treated with both continuous and intermittent therapy (5 mg/kg daily) for up to 1 year. Patients treated with this agent should have their dose titrated to the lowest
effective dose after the disease is brought under control with appropriate monitoring, under the care of a specialist familiar with the drug. Mycophenolate mofetil has also been shown to be safe and effective in children with severe atopic dermatitis although this was a retrospective case series.

Ultraviolet light therapy can be useful for chronic recalcitrant atopic dermatitis in a subset of patients under the supervision of a dermatologist. Photochemotherapy with oral methoxypsoralen therapy followed by UVA (ultraviolet A) has been used in a limited number of children with severe atopic dermatitis unresponsive to other therapy, and significant improvement has been noted. However, the increased long-term risk of cutaneous malignancies from this therapy prevents its widespread use.

K. Experimental and Unproved Therapies

Subcutaneous desensitization to dust mite allergen has been shown to improve atopic dermatitis in adult patients and one blinded, placebo-controlled study of sublingual desensitization in dust mite allergic children showed benefit in mild-moderate atopic dermatitis (currently not FDA approved); however, further controlled trials are needed before this form of therapy can be recommended for atopic dermatitis in children. Treatment of atopic dermatitis with high-dose intravenous immunoglobulin and omalizumab is currently investigational. Although disturbances in the metabolism of essential fatty acids have been reported in patients with atopic dermatitis, controlled trials with fish oil and evening primrose have shown no clinical benefit.

Prognosis

While many children, especially those with mild disease will outgrow their atopic dermatitis, patients with filaggrin gene mutations are more likely to have more persistent and severe disease. In addition, these patients appear to be the ones at greater risk for developing asthma and allergic sensitizations.

About half of patients will have concomitant urticaria and angioedema, whereas 40% will have only urticaria and 10% only angioedema. Urticarial lesions are arbitrarily designated as acute, lasting less than 6 weeks, or chronic, lasting more than 6 weeks. Acute versus chronic urticaria can also be distinguished by differences in histologic features. A history of atopy is common with acute urticaria or angioedema. In contrast, atopy does not appear to be a factor in chronic urticaria. Note that bradykinin-mediated hereditary angioedema is discussed in the immunodeficiency chapter (Chapter 33).

Mast cell degranulation, dilated venules, and dermal edema are present in most forms of urticaria or angioedema. The dermal inflammatory cells may be sparse or dense depending on the chronicity of the lesions. Mast cells are thought to play a critical role in the pathogenesis of urticaria or angioedema through release of a variety of vasoactive mediators. Mast cell activation and degranulation can be triggered by different stimuli, including cross-linking of Fc receptor–bound IgE by allergens or anti-FcεRI antibodies. Non–IgE-mediated mechanisms have also been identified, including complement anaphylatoxins (C3a, C5a), radiocontrast dyes, and physical stimuli. Chronic urticarial lesions have greater numbers of perivascular mononuclear cells, consisting primarily of T cells. There is also a marked increase in cutaneous mast cells.

The cause of acute disease can be identified in about half of patients and includes allergens such as foods, aeroallergens, latex, drugs, and insect venoms. Infectious agents, including streptococci, mycoplasmas, hepatitis B virus, and Epstein-Barr virus, can cause acute urticaria. Urticaria or angioedema can occur after the administration of blood products or immunoglobulin. This results from immune complex formation with complement activation, vascular alterations, and triggering of mast cells by anaphylatoxins. Opiate analgesics, polymyxin B, tubocurarine, and radiocontrast media can induce acute urticaria by direct mast cell activation. These disorders can also occur following ingestion of aspirin or nonsteroidal anti-inflammatory agents (see later section on Adverse Reactions to Drugs & Biologicals).

Physical urticarias represent a heterogeneous group of disorders in which urticaria or angioedema is triggered by physical stimuli, including pressure, cold, heat, water, or vibrations. Dermographism is the most common form of physical urticaria, affecting up to 4% of the population and occurring at skin sites subjected to mechanical stimuli. Many physical urticarias are considered to be acute because the lesions are usually rapid in onset, with resolution within hours. However, symptoms can recur for months to years.

The cause of chronic urticaria is usually not due to allergies and typically cannot be determined. It can be associated with autoimmunity, such as autoimmune thyroid disease, or the presence of basophil-activating IgG autoantibodies directed at the high-affinity receptor for IgE or at IgE.

URTICARIA & ANGIOEDEMA

General Considerations

Urticaria and angioedema are common dermatologic conditions, occurring at some time in up to 25% of the population.

Clinical Findings

A. Symptoms and Signs

Cold-induced urticaria or angioedema can occur within minutes of exposure to a decreased ambient temperature or as the skin is warmed following direct cold contact. Systemic features include headache, wheezing, and syncope. If the entire body is cooled, as may occur during swimming, hypotension and collapse can occur. Two forms of dominantly inherited cold urticaria have been described. The immediate form is known as familial cold urticaria, in which erythematous macules appear rather than wheals, along with fever, arthralgias, and leukocytosis. The delayed form consists of erythematous, deep swellings that develop 9–18 hours after local cold challenge without immediate lesions.

In solar urticaria, which occurs within minutes after exposure to light of appropriate wavelength, pruritus is followed by morbilliform erythema and urticaria.

Cholinergic urticaria occurs after increases in core body and skin temperatures and typically develops after a warm bath or shower, exercise, or episodes of fever. Occasional episodes are triggered by stress or the ingestion of certain foods. The eruption appears as small punctate wheals surrounded by extensive areas of erythema. Rarely, the urticarial lesions become confluent and angioedema develops. Associated features can include one or more of the following: headache, syncope, bronchospasm, abdominal pain, vomiting, and diarrhea. In severe cases, systemic anaphylaxis may develop.

In pressure urticaria or angioedema, red, deep, painful swelling occurs immediately or 4–6 hours after the skin has been exposed to pressure. The immediate form is often associated with dermographism. The delayed form, which may be associated with fever, chills, and arthralgias, may be accompanied by elevated erythrocyte sedimentation rate and leukocytosis. Lesions are frequently diffuse, tender, and painful rather than pruritic. They typically resolve within 48 hours.

B. Laboratory Findings

Laboratory tests are selected on the basis of the history and physical findings. Testing for specific IgE antibody to food or inhalant allergens may be helpful in implicating a potential cause. Specific tests for physical urticarias, such as an ice cube test or a pressure test, may be indicated. Intradermal injection of methacholine reproduces clinical symptoms locally in about one-third of patients with cholinergic urticaria. A throat culture for streptococcal infection may be warranted with acute urticaria. In chronic urticaria, selected screening studies to look for an underlying disease may be indicated, including a complete blood count, erythrocyte sedimentation rate, biochemistry panel, and urinalysis. Antithyroid antibodies may be considered. Intradermal testing with the patient’s serum has been suggested as a method of detecting histamine-releasing activity, including autoantibodies (autologous serum skin test). In patients with well-characterized autoimmune urticaria, donor basophil and mast cell activation markers including CD63 and CD203c have been shown to be upregulated in patient serum. Other tests should be done based on suspicion of a specific underlying disease. If the history or appearance of the urticarial lesions suggests vasculitis, a skin biopsy for immunofluorescence is indicated. Patient diaries occasionally may be helpful to determine the cause of recurrent hives. A trial of food or drug elimination may be considered.

Differential Diagnosis

Urticarial lesions are usually easily recognized—the major dilemma is the etiologic diagnosis. Lesions of urticarial vasculitis typically last for more than 24 hours. “Papular urticaria” is a term used to characterize multiple papules from insect bites, found especially on the extremities, and is not true urticaria. Angioedema can be distinguished from other forms of edema because it is transient, asymmetrical, and nonpitting and does not occur predominantly in dependent areas. Hereditary angioedema is a rare autosomal dominant disorder caused by a quantitative or functional deficiency of C1-esterase inhibitor and characterized by episodic, frequently severe, nonpruritic angioedema of the skin, gastrointestinal tract, or upper respiratory tract (discussed in Chapter 33). Life-threatening laryngeal angioedema may occur. Rare autoinflammatory disorders with urticaria or urticaria-vasculitic-like lesions include cold-induced autoinflammatory syndrome, Muckle-Wells syndrome, and Schnitzler syndrome.

Complications

In severe cases of cholinergic urticaria, systemic anaphylaxis may develop. In cold-induced disease, sudden cooling of the entire body as can occur with swimming can result in hypotension and collapse.

Treatment

A. General Measures

The most effective treatment is identification and avoidance of the triggering agent. Underlying infection should be treated appropriately. Patients with physical urticarias should avoid the relevant physical stimulus. Patients with cold urticaria should be counseled not to swim alone and prescribed autoinjectable epinephrine in case of generalized mast cell degranulation with immersion in cold water or other widespread cold exposures.

B. Antihistamines

For the majority of patients, H1 antihistamines given orally or systemically are the mainstay of therapy. Antihistamines
are more effective when given on an ongoing basis rather than after lesions appear. Second-generation antihistamines (discussed previously under Allergic Rhinconjunctivitis) are long acting, show good tissue levels, are non- or minimally sedating at usual dosing levels, and lack anticholinergic effects. They are the preferred treatment for treating urticaria. The addition of H₂ antihistamines may benefit some patients who fail to respond to H₁-receptor antagonists alone. In school-aged children, but especially adolescents who are of driving age or who operate machinery, nonseating antihistamines should be used during the day and sedating antihistamines can be added at bedtime, if needed. Patients with urticaria may require treatment with higher than usual doses of antihistamines if they have breakthrough symptoms.

C. Corticosteroids

Although corticosteroids are usually not indicated in the treatment of acute or chronic urticaria, severe recalcitrant cases may require alternate-day or low dose therapy in an attempt to diminish disease activity or short-term use to facilitate control with antihistamines. However, high-dose chronic steroid use should be avoided. Systemic corticosteroids may also be needed in the treatment of urticaria or angioedema secondary to necrotizing vasculitis, an uncommon occurrence in patients with serum sickness or collagen-vascular disease.

D. Other Pharmacologic Agents

Limited studies suggest that some patients may benefit from treatment with a leukotriene-receptor antagonist. The tricyclic antidepressant doxepin blocks both H₁ and H₂ histamine receptors and may be particularly useful in chronic urticaria, although its use may be limited by the sedating side effect. Cyclosporine has been shown to be effective in multiple trials of severe chronic urticaria, but it does require blood pressure and renal function monitoring. Omalizumab trials for refractory chronic urticaria have shown promising results, but it is not currently FDA-approved for this condition. A limited number of patients—including euthyroid patients—with chronic urticaria and antithyroid antibodies have improved when given thyroid hormone, although this treatment remains controversial. Treatment of chronic urticaria with hydroxychloroquine, sulfasalazine, dapsone, colchicine, and intravenous immune globulin should be considered investigational.

Prognosis

Spontaneous remission of urticaria and angioedema is frequent, but some patients have a prolonged course, especially those with physical urticaria. In one natural history study, approximately 58% of children with chronic urticaria became symptom free after 6 months. Reassurance is important, because this disorder can cause significant frustration. Periodic follow-up is indicated, particularly for patients with laryngeal edema, to monitor for possible underlying cause.

ANAPHYLAXIS

General Considerations

Anaphylaxis is an acute life-threatening clinical syndrome that occurs when large quantities of inflammatory mediators are rapidly released from mast cells and basophils after exposure to an allergen in a previously sensitized patient. Anaphylactoid reactions mimic anaphylaxis but are not mediated by IgE antibodies. They may be mediated by anaphylatoxins such as C3a or C5a or through nonimmune mast cell degranulating agents. Some of the common causes of anaphylaxis or anaphylactoid reactions are listed in Table 38–6. Idiopathic anaphylaxis by definition has no recognized external cause. The clinical history is the most important tool in making the diagnosis of anaphylaxis.

Table 38–6. Common causes of systemic allergic and pseudoallergic reactions.
Clinical Findings

A. Symptoms and Signs

The history is the most important tool to determine whether a patient has had anaphylaxis. The symptoms and signs of anaphylaxis depend on the organs affected. Onset typically occurs within minutes after exposure to the offending agent and can be short-lived, protracted, or biphasic, with recurrence after several hours despite treatment.

Anaphylaxis is highly likely when any one of the following three criteria is fulfilled:

1. Acute onset of an illness (minutes to several hours) with involvement of the skin, mucosal tissue, or both (eg, generalized hives, pruritus or flushing, swollen lips-tongue-uvula) and at least one of the following:
   a. Respiratory compromise (eg, dyspnea, wheeze, bronchospasm, stridor, reduced peak expiratory flow, hypoxemia)
   b. Reduced blood pressure or associated symptoms of end-organ dysfunction (eg, hypotonia [collapse], syncope, incontinence)

2. Two or more of the following that occur rapidly after exposure to a likely allergen for that patient (minutes to several hours):
   a. Involvement of the skin-mucosal tissue (eg, generalized urticaria, itch-flush, swollen lips-tongue-uvula)
   b. Respiratory compromise (eg, dyspnea, wheeze, bronchospasm, stridor, reduced PEFR, hypoxemia)
   c. Reduced blood pressure or associated symptoms (eg, hypotonia [collapse], syncope, incontinence)
   d. Persistent gastrointestinal symptoms (eg, crampy abdominal pain, vomiting)

3. Reduced blood pressure after exposure to a known allergen for that patient (minutes to several hours)
   a. Infants and children: low systolic blood pressure (age specific) or greater than 30% decrease in systolic pressure
   b. Low systolic blood pressure in children, defined as less than 70 mm Hg in those aged from 1 month to 1 year, less than (70 mm Hg + [2 × age]) in those 1–10 years of age, and less than 90 mm Hg in those 11–17 years

B. Laboratory Findings

An absence of laboratory findings does not rule out anaphylaxis. Tryptase released by mast cells can be measured in the serum and may be helpful when the diagnosis of anaphylaxis is in question. The blood sample should be obtained within 3 hours of onset of the reaction, although tryptase levels are often normal, particularly in individuals with food-induced anaphylaxis. The complete blood count may show an elevated hematocrit due to hemoconcentration. Elevation of serum creatine kinase, aspartate aminotransferase, and lactic dehydrogenase may be seen with myocardial involvement. Electrocardiographic abnormalities may include ST-wave depression, bundle branch block, and various arrhythmias. Arterial blood gases may show hypoxemia, hypercapnia, and acidosis. The chest radiograph may show hyperinflation.

Differential Diagnosis

Although shock may be the only sign of anaphylaxis, other diagnoses should be considered, especially in the setting of sudden collapse without typical allergic findings. Other causes of shock along with cardiac arrhythmias must be ruled out (see Chapters 12 and 14). Respiratory failure associated with asthma may be confused with anaphylaxis. Mastocytosis, hereditary angioedema, scombroid poisoning, vasovagal reactions, vocal cord dysfunction, and anxiety attacks may cause symptoms mistaken for anaphylaxis.

Complications

Depending on the organs involved and the severity of the reaction, complications may vary from none to asthmatic pneumonia, acute tubular necrosis, bleeding diathesis, or sloughing of the intestinal mucosa. With irreversible shock, heart and brain damage can be terminal. Risk factors for fatal or near-fatal anaphylaxis include age (adolescents and young adults), reactions to peanut or tree nuts, associated asthma, strenuous exercise, and ingestion of medications such as β-blockers.

Prevention

Strict avoidance of the causative agent is extremely important. An effort to determine its cause should be made, beginning with a thorough history. Typically, there is a strong temporal relationship between exposure and onset of symptoms. Testing for specific IgE to allergens with either in vitro or skin testing may be indicated. With exercise-induced anaphylaxis, patients should be instructed to exercise with another person and to stop exercising at the first sign of symptoms. If prior ingestion of food has been implicated, eating within 4 hours—perhaps up to 12 hours—before exercise should be avoided. Patients with a history of anaphylaxis should carry epinephrine for self-administration, preferably in the form of an autoinjector (eg, Auvi-Q or EpiPen in 0.15- and 0.3-mg doses), and they and all caregivers should be instructed on its use. When epinephrine autoinjectors are unavailable or unaffordable, patients in some communities have been provided with unsealed syringes containing premeasured epinephrine doses, but this is not the recommended form since it needs to be replaced every few months on a regular basis due to lack of stability and the use of a syringe is more unwieldy in an emergent situation. They should also carry an oral antihistamine such as diphenhydramine, preferably in liquid or fast-melt preparation to hasten absorption, and consider wearing...
a medical alert bracelet. Patients with idiopathic anaphylaxis may require prolonged treatment with oral corticosteroids. Specific measures for dealing with food, drug, latex, and insect venom allergies as well as radiocontrast media reactions are discussed in the next sections.

**Treatment**

**A. General Measures**

Anaphylaxis is a medical emergency that requires rapid assessment and treatment. Exposure to the triggering agent should be discontinued. Airway patency should be maintained and blood pressure and pulse monitored. Simultaneously and promptly, emergency medical services or a call for help to a resuscitation team should be made. The patient should be placed in a supine position with the legs elevated unless precluded by shortness of breath or emesis. Oxygen should be delivered by mask or nasal cannula with pulse oximetry monitoring. If the reaction is secondary to a sting or injection into an extremity, a tourniquet may be applied proximal to the site, briefly releasing it every 10–15 minutes.

**B. Epinephrine**

Epinephrine is the treatment of choice for anaphylaxis. Epinephrine 1:1000, 0.01 mg/kg to a maximum of 0.5 mg in adults and 0.3 mg in children, should be injected intramuscularly in the midanterolateral thigh, without delay. This dose may be repeated at intervals of 5–15 minutes as necessary for controlling symptoms and maintaining blood pressure. If the precipitating allergen has been injected intradermally or subcutaneously, absorption may be delayed by giving 0.1 mL of epinephrine subcutaneously at the injection site unless the site is a digit. There is no precisely established dosing regimen for intravenous epinephrine in anaphylaxis, but a 5–10 mcg intravenous bolus for hypotension and 0.1–0.5 mg intravenously for cardiovascular collapse has been suggested.

**C. Antihistamines**

Diphenhydramine, an H₁-blocker, 1–2 mg/kg up to 50 mg, can be given orally, intramuscularly or intravenously. Intravenous antihistamines should be infused over a period of 5–10 minutes to avoid inducing hypotension. Alternatively in young patients, cetirizine 0.25 mg/kg to a maximum dose of 10 mg could be given orally, as it was shown to have a longer duration of action and reduced sedation profile. Addition of ranitidine, an H₂-blocker, 1 mg/kg up to 50 mg intravenously, may be more effective than an H₁-blocker alone, especially for hypotension, but histamine blockers should be considered second-line treatment for anaphylaxis.

**D. Fluids**

Treatment of persistent hypotension despite epinephrine requires restoration of intravascular volume by fluid replacement, initially with a crystalloid solution, 20–30 mL/kg in the first hour.

**E. Bronchodilators**

Nebulized β₂-agonists such as albuterol 0.5% solution, 2.5 mg (0.5 mL) diluted in 2–3 mL saline, or levalbuterol, 0.63 mg or 1.25 mg, may be useful for reversing bronchospasm. Intravenous methylxanthines are generally not recommended because they provide little benefit over inhaled β₂-agonists and may contribute to toxicity.

**F. Corticosteroids**

Although corticosteroids do not provide immediate benefit, when given early they may prevent protracted or biphasic anaphylaxis. Intravenous methylprednisolone, 50–100 mg (adult) or 1 mg/kg, maximum 50 mg (child), can be given every 4–6 hours. Oral prednisone, 1 mg/kg up to 50 mg, might be sufficient for less severe episodes.

**G. Vaspressors**

Hypotension refractory to epinephrine and fluids should be treated with intravenous vasopressors such as noradrenaline, vasopressin, or dopamine (see Chapter 14).

**H. Observation**

The patient should be monitored after the initial symptoms have subsided, because biphasic or protracted anaphylaxis can occur despite ongoing therapy. Biphasic reactions occur in 1%–20% of anaphylactic reactions, but no reliable clinical predictors have been identified. Observation periods should be individualized based on the severity of the initial reaction, but a reasonable time for observation is 4–6 hours in most patients, with prolonged observation or admission for severe or refractory symptoms.

**Prognosis**

Anaphylaxis can be fatal. In two reports describing children, adolescents, and adults who died from food-induced anaphylaxis (eg, from peanuts, tree nuts, fish, shellfish, and milk) over the past 12 years, treatment with epinephrine was delayed for more than 1 hour after onset as it was not readily accessible in the majority of subjects. The prognosis, however, is good when signs and symptoms are recognized promptly and treated aggressively, and the offending agent is subsequently avoided. Exercise-induced and idiopathic anaphylaxis may be recurrent. Because accidental exposure to the causative agent may occur, patients, parents, and
caregivers must be prepared to recognize and treat anaphylaxis (emergency action plan).

ADVERSE REACTIONS TO DRUGS & BIOLOGICALS

The majority of adverse drug reactions are not immunologically mediated and may be due to idiosyncratic reactions, overdosage, pharmacologic side effects, non-specific release of pharmacologic effector molecules, or drug interactions.

Patients or caregivers often label any adverse drug reaction as an “allergy.” Adverse drug reactions are any undesirable and unintended response elicited by a drug. Allergic or hypersensitivity drug reactions are adverse reactions involving immune mechanisms. Although hypersensitivity reactions account for only 5%–10% of all adverse drug reactions, they are the most serious, with 1:10,000 resulting in death. Clinicians can report adverse drug reactions and get updated information on drugs, vaccines, and biologics at the FDA’s MedWatch website.

1. Antibiotics

Antibiotics constitute the most frequent cause of allergic drug reactions. Amoxicillin, trimethoprim–sulfamethoxazole, and ampicillin are the most common causes of cutaneous drug reactions.

Most antibiotics and their metabolites are low-molecular-weight compounds that do not stimulate immunity until they have become covalently bound to a carrier protein. The penicillins and other β-lactam antibiotics, including cephalosporins, carbacephems, carbapenems, and monobactams, share a common β-lactam ring structure and a marked propensity to couple to carrier proteins. Penicilloyl is the predominant metabolite of penicillin and is called the major determinant. The other penicillin metabolites are present in low concentrations and are referred to as minor determinants. Sulfonamide reactions are mediated presumably by a reactive metabolite (hydroxylamine) produced by cytochrome P-450 oxidative metabolism. Slow acetylators appear to be at increased risk. Other risk factors for drug reactions include previous exposure, previous reaction, age (20–49 years), route (parenteral), and dose of administration (high, intermittent). Atopy does not predispose to development of a reaction, but atopic individuals have more severe reactions.

Immunopathologic reactions to antibiotics include type I (IgE-mediated) reactions resulting from a drug or metabolite interaction with preformed specific IgE bound to the surfaces of tissue mast cells or circulating basophils. Release of mediators such as histamine and leukotrienes contributes to the clinical development of angioedema, urticaria, bronchospasm, or anaphylaxis immediately after the dose. Type II (cytotoxic) reactions involve IgG or IgM antibodies that recognize drug bound to cell membranes. In the presence of serum complement, the antibody-coated cell is either cleared or destroyed, causing drug-induced hemolytic anemia or thrombocytopenia. Type III (immune complex) reactions are caused by soluble complexes of drug or metabolite with IgG or IgM antibody. If the immune complex is deposited on blood vessel walls and activates the complement cascade, serum sickness may result. Type IV (T-cell–mediated) reactions require activated T lymphocytes that recognize a drug or its metabolite as seen in allergic contact dermatitis. Sensitization usually occurs via the topical route of administration. Immunopathologic reactions not fitting into the types I–IV classification include Stevens-Johnson syndrome, exfoliative dermatitis, and the maculopapular rash associated with penicillin or ampicillin. The prevalence of morbilliform rashes in patients given ampicillin is between 5.2% and 9.5% of treatment courses. However, patients given ampicillin during Epstein-Barr virus and cytomegalovirus infections or with acute lymphoblastic anemia have a 69%–100% incidence of non–IgE-mediated rash. Serum sickness–like reactions resemble type III reactions, although immune complexes are not documented; β-lactams, especially cefaclor, and sulfonamides have been implicated most often. They may result from an inherited propensity for hepatic biotransformation of drug into toxic or immunogenic metabolites. The incidence of “allergic” cutaneous reactions to trimethoprim–sulfamethoxazole in patients with AIDS has been reported to be as high as 70%. The mechanism is thought to relate to severe immune dysregulation, although it may be due to glutathione deficiency resulting in toxic metabolites.

Clinical Findings

A. Symptoms and Signs

Allergic reactions can result in pruritus, urticaria, angioedema, or anaphylaxis. Serum sickness is characterized by fever, rash, lymphadenopathy, myalgias, and arthralgias. Cytotoxic drug reactions can result in symptoms and signs associated with the underlying anemia or thrombocytopenia. Delayed-type hypersensitivity may cause contact dermatitis.

B. Laboratory Findings

Skin testing is the most rapid, useful, and sensitive method of demonstrating the presence of IgE antibody to
a specific allergen. Skin testing to nonpenicillin antibiotics may be difficult, however, because many immunologic reactions are due to metabolites rather than to the parent drug and because the relevant metabolites for most drugs other than penicillin have not been identified. Because metabolites are usually low-molecular-weight haptenst, they must combine with carrier proteins to be useful for diagnosis. Skin testing for immediate hypersensitivity is helpful only in predicting reactions caused by IgE antibodies. Most nonpruritic maculopapular rashes will not be predicted by skin testing. In the case of contact sensitivity reactions to topical antibiotics, a 48-hour patch test can be useful.

Solid-phase in vitro immunoassays for IgE to penicillins are available for identification of IgE to penicilloyl, but are considerably less sensitive than skin testing and the predictive values are not known. Assays for specific IgG and IgM have been shown to correlate with a drug reaction in immune cytopenias, but in most other instances such assays are not clinically useful. Approximately 80% of patients with a history of penicillin allergy will have negative skin tests. Penicillin therapy in patients with a history of an immediate hypersensitivity reaction to penicillin, but with negative skin tests to both penicilloyl and the minor determinant mixture, is accompanied by a 1%–3% chance of urticaria or other mild allergic reactions at some time during therapy, with anaphylaxis occurring in less than 0.1% of patients. In contrast, the predictive value of a positive skin test is approximately 60%. Testing with penicilloyl linked to polylysine (PPL) alone has a sensitivity of about 76%; use of both PPL and penicillin G (used as a minor determinant) increases sensitivity to about 95%. Not using the minor determinant mixture in skin testing can result in failure to predict potential anaphylactic reactions. Unfortunately, the minor determinant mixture is still not commercially available, although some academic allergy centers make their own. Approximately 4% of subjects tested who have no history of penicillin allergy have positive skin tests. Rarely, patients may have skin test reactivity only to a specific semisynthetic penicillin. Resensitization in skin test–negative children occurs infrequently (<1%) after a course of oral antibiotic. Of note, the manufacturing of the major determinant of penicillin testing reagent Pre-Pen (penicilloyl-polylysine) in the United States was discontinued for several years. AllerQuest received approval from the FDA in January 2008 to manufacture Pre-Pen and the product is once again available (distributed by ALK-Abello, Inc).

The degree of cross-reactivity of determinants formed from cephalosporins with IgE to other β-lactam drugs remains unresolved, especially because haptenst that may be unique to cephalosporin metabolism remain unknown. The degree of clinical cross-reactivity is much lower than the in vitro cross-reactivity. A clinical adverse reaction rate of 3%–7% for cephalosporins may be expected in patients with a history of immediate reaction to penicillins with positive skin tests to penicillin. Antibodies to the second, third, and fourth generation cephalosporins appear to be directed at the unique side chains rather than at the common ring structure. The present literature suggests that a positive skin test to a cephalosporin used at a concentration of 1 mg/mL would place the patient at increased risk for an allergic reaction to that antibiotic. However, a negative skin test would not exclude sensitivity to a potentially relevant metabolite. One review concluded that there is no increased incidence of allergy to second- and third-generation cephalosporins in patients with penicillin allergy and that penicillin skin testing does not identify patients who develop cephalosporin allergy. However, another study suggested that although only 2% of penicillin-allergic patients would react to a cephalosporin, they would be at risk for anaphylaxis.

Carbacephems (loracarbef) are similar to cephalosporins, although the degree of cross-reactivity is undetermined. Carbapenems (imipenem) represent another class of β-lactam antibiotics with a bicyclic nucleus and a high degree of cross-reactivity with penicillin although recent prospective studies suggest an incidence of cross-reactivity on skin testing of approximately 1%. Monobactams (aztreonam) contain a monocyclic rather than bicyclic ring structure, and limited data suggest that aztreonam can be safely administered to most penicillin-allergic subjects. In contrast, administration of aztreonam to a patient with ceftazidime allergy may be associated with increased risk of allergic reaction due to similarity of side chains.

Skin testing for non–β-lactam antibiotics is less reliable, because the relevant degradation products are for the most part unknown or multivalent reagents are unavailable.

**Treatment**

**A. General Measures**

Withdrawal of the implicated drug is usually a central component of management. Acute IgE-mediated reactions such as anaphylaxis, urticaria, and angioedema are treated according to established therapeutic guidelines that include the use of epinephrine, H1- and H2-receptor blocking agents, volume replacement, and systemic corticosteroids (see previous sections). Antibiotic-induced immune cytopenias can be managed by withdrawal of the offending agent or reduction in dose. Drug-induced serum sickness can be suppressed by drug withdrawal, antihistamines, and corticosteroids. Contact allergy can be managed by avoidance and treatment with antihistamines and topical corticosteroids. Reactions such as toxic epidermal necrolysis and Stevens-Johnson syndrome require immediate drug withdrawal and supportive care.

**B. Alternative Therapy**

If possible, subsequent therapy should be with an alternative drug that has therapeutic actions similar to the drug in question but with no immunologic cross-reactivity.
C. Desensitization

Administering gradually increasing doses of an antibiotic either orally or parenterally over a period of hours to days may be considered if alternative therapy is not acceptable. This should be done only by a physician familiar with desensitization, typically in an intensive care setting. Of note, desensitization is only effective for the course of therapy for which the patient was desensitized, unless maintained on a chronic prophylactic dose of the medication as patients revert from a desensitized to allergic state after the drug is discontinued. In addition, desensitization does not reduce or prevent non–IgE-mediated reactions. Patients with Stevens-Johnson syndrome should not be desensitized because of the high mortality rate.

Prognosis

The prognosis is good when drug allergens are identified early and avoided. Stevens-Johnson syndrome and toxic epidermal necrolysis may be associated with a high mortality rate.

2. Latex Allergy

General Considerations

Allergic reactions to latex and rubber products have become increasingly common since the institution of universal precautions for exposure to bodily fluids. Children with spina bifida appear to have a unique sensitivity to latex, perhaps because of early and frequent latex exposure as well as altered neuroimmune interactions. Atopy—especially symptomatic latex allergy—appears to be significantly increased in patients with spina bifida experiencing anaphylaxis during general anesthesia. Other conditions requiring chronic or recurrent exposure to latex such as urogenital anomalies and ventriculoperitoneal shunt have also been associated with latex hypersensitivity. The combination of atopy and frequent exposure seems to synergistically increase the risk of latex hypersensitivity.

Latex is the milky fluid obtained by tapping the cultivated rubber tree, *Hevea brasiliensis*. During manufacture of latex products, various antioxidants and accelerators such as thiurams, carbamates, and mercaptobenzothiazoles are added. IgE from latex-sensitized individuals reacts with different protein components, supporting the notion that more than one clinically important latex antigen exists. New allergenic epitopes are generated during the manufacturing process. Thus, polypeptides from latex glove extracts vary both quantitatively and qualitatively with different brands and lots of gloves. Identification of the causative antigens is important because it may be possible to alter the manufacturing process to reduce the final allergen content.

Latex is ubiquitous in medical settings, and many sources may be inconspicuous. Synthetic alternatives to some latex products—including gloves, dressings, and tape—are available. Avoidance of contact with latex-containing items, however, may be insufficient to prevent allergic reactions, because lubricating powders may serve as vehicles for aerosolized latex antigens. The use of powder-free latex gloves is an important control measure for airborne latex allergen.

Nonmedical sources of latex are also common and include balloons, toys, rubber bands, erasers, condoms, and shoe soles. Pacifiers and bottle nipples have also been implicated as sources of latex allergen, although these products are molded rather than dipped, and allergic reactions to molded products are less common. Latex-allergic patients and their caregivers must be continuously vigilant for hidden sources of exposure.

Clinical Findings

A. Symptoms and Signs

The clinical manifestations of IgE-mediated reactions to latex can involve the full spectrum of symptoms associated with mast cell degranulation. Localized pruritus and urticaria occur after cutaneous contact; conjunctivitis and rhinitis can result from aerosol exposure or direct facial contact. Systemic reactions, including bronchospasm, laryngospasm, and hypotension, may occur with more substantial exposure or in extremely sensitive individuals. Finally, vascular collapse and shock leading to fatal cardiovascular events may occur. Intraoperative anaphylaxis represents a common and serious manifestation of latex allergy.

Allergic contact dermatitis to rubber products typically appears 24–48 hours after contact. The primary allergens include accelerators and antioxidants used in the manufacturing process. The diagnosis is established by patch testing. Shoe soles are an important source of exposure. The skin lesions appear primarily as a patchy eczema on exposed surfaces, although reactions can become generalized.

B. Laboratory Findings

Epicutaneous prick testing is a rapid, inexpensive, and sensitive test that detects the presence of latex-specific IgE on skin mast cells although a standardized antigen is not yet commercially available. Reports of life-threatening anaphylactic events have been associated with skin testing to latex, and intradermal testing may be especially dangerous.

Immunoassay testing involves the in vitro measurement of specific IgE, which binds latex antigens. Antigen sources used for testing have included native plant extracts, raw latex, and finished products. When compared with a history of latex-induced symptoms or positive skin tests, the sensitivity of immunoassays testing for latex antigens ranges from 50% to 100% with specificity between 63% and 100%. These broad ranges may reflect the patient population studied and the source of latex antigen as well as the assay employed. A positive immunoassay test to latex in the presence of a highly suggestive latex allergy history is useful and may circumvent...
the potential concerns associated with prick skin testing in certain patients. Patch testing with standardized T.R.U.E. Test or other sources of antigens can identify antigens used in the manufacturing of latex products that can cause allergic contact dermatitis.

Cross-reactivity has been demonstrated between latex and a number of other antigens such as foods. Banana, avocado, and chestnut have been found to be antigenically similar to latex both immunologically and clinically.

**Complications**

Complications may be similar to those caused by other allergens. Prolonged exposure to aerosolized latex may lead to persistent asthma. Chronic allergic contact dermatitis, especially on the hands, can lead to functional disability.

**Treatment**

Avoidance remains the cornerstone of treatment for latex allergy. Prevention and supportive therapy are the most common methods for managing this problem. Patients identified as being allergic to latex may need to have a personal supply of vinyl or latex-free gloves for use when visiting a physician or dentist. “Hypoallergenic gloves” are poorly classified with respect to their ability to induce IgE-mediated reactions; the FDA currently uses this term to designate products that have a reduced capacity to induce contact dermatitis. Nonlatex gloves include nitrile and vinyl ones. A glove made from guayule latex has been approved by the FDA. Autoinjectable epinephrine and medical identification bracelets may be prescribed for latex-allergic patients along with avoidance counseling.

Prophylactic premedication of latex-allergic individuals has been used in some surgical patients at high risk for latex allergy. The rationale for this therapy is derived from the pretreatment protocols developed for iodinated radiocontrast media and anesthetic reactions. Although there has been some success using this regimen, anaphylaxis has occurred despite pretreatment. This approach should not substitute for careful avoidance measures.

**Prognosis**

Owing to the ubiquitous nature of natural rubber, the prognosis is guarded for patients with severe latex allergy. Chronic exposure to airborne latex particles may lead to chronic asthma. Chronic dermatitis can lead to functional disability.

**3. Vaccines**

Mumps-measles-rubella (MMR) vaccine has been shown to be safe in egg-allergic patients (although rare reactions to gelatin or neomycin can occur). Although the amount of ovalbumin in influenza vaccine is variable, content does not appear to predict risk of reaction and several studies suggest that egg allergic children can safely receive influenza vaccine injection as a single full dose. Skin prick testing and graded dosing is no longer recommended for egg-allergic patients who have not reacted to the influenza vaccine. Egg allergic patients should be observed for 30 minutes after receiving influenza vaccine and if there are concerns about administration, they should be referred to an allergist. In addition, the live intranasal influenza vaccine has not been studied in egg-allergic children so its safety is unknown.

**4. Radiocontrast Media**

Non–IgE-mediated anaphylactoid reactions may occur with radiocontrast media with up to a 30% reaction rate on reexposure. Management involves using a low-molarity agent and premedication with prednisone, diphenhydramine, and possibly an H₂-blocker.

**5. Insulin**

Approximately 50% of patients receiving insulin have positive skin tests, but IgE-mediated reactions occur rarely. Insulin resistance is mediated by IgG. If less than 24 hours has elapsed after an allergic reaction to insulin, do not discontinue insulin but rather reduce the dose by one-third, then increase by 2–5 units per injection. Skin testing and desensitization are necessary if the interval between the allergic reaction and subsequent dose is greater than 24 hours.

**6. Local Anesthetics**

Less than 1% of reactions to local anesthetics are IgE-mediated. Management involves selecting a local anesthetic from another class. Esters of benzoic acid include benzocaine and procaine; amides include lidocaine and mepivacaine. Alternatively, the patient can be skin tested with the suspected agent, followed by a provocative challenge. To rule out paraben sensitivity, skin testing can be done with 1% lidocaine from a multidose vial.

**7. Aspirin & Other Nonsteroidal Anti-Inflammatory Drugs**

Adverse reactions to aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) include urticaria and angioedema; rhinosinusitis, nasal polyps, and asthma (Aspirin-exacerbated respiratory disease AERD); anaphylactoid reactions; and NSAID-related hypersensitivity pneumonitis. After a systemic reaction, a refractory period of 2–7 days occurs. Most aspirin-sensitive patients tolerate sodium salicylate. All NSAIDs inhibiting cyclooxygenase (COX) cross-react with aspirin. Cross-reactivity between aspirin and tartrazine (yellow dye No. 5) has not been substantiated in controlled trials. No skin test or in vitro test is available to
diagnose aspirin sensitivity. Oral challenge can induce severe bronchospasm in AERD patients. Aspirin desensitization can be performed to ameliorate the symptoms of AERD. Desensitization and cross-desensitization to NSAIDs can be achieved in most patients and maintained for a long term. Leukotriene-receptor antagonists or 5-lipoxygenase inhibitors attenuate the reaction to aspirin challenge and may be beneficial adjunct treatment in aspirin-sensitive asthmatic patients. COX-2 inhibitors are tolerated by patients with AERD.

8. Biological Agents

In recent years, a growing number of biological agents have become available for the treatment of autoimmune, neoplastic, cardiovascular, infectious, and allergic diseases, among others. Their use may be associated with a variety of adverse reactions, including hypersensitivity reactions. The FDA issued a boxed warning regarding risk of anaphylaxis and need for patient monitoring with use of omalizumab (see section on Pharmacologic Therapy under Treatment, Chronic Asthma, earlier). Updated information can be found at the FDA’s MedWatch website under Vaccines, Blood, and Biologics.

9. Hypersensitivity to Retroviral Agents

Adverse drug reactions are being reported with increasing frequency to antiretroviral agents, including reverse transcriptase inhibitors, protease inhibitors, and fusion inhibitors. Hypersensitivity to abacavir is a well-described, multiorgan, potentially life-threatening reaction that occurs in HIV-infected children. The reaction is independent of dose with onset generally within 9–11 days of initiation of drug therapy. Rechallenge can be accompanied by significant hypotension and given a mortality rate of 0.03%; hypersensitivity to abacavir is an absolute contraindication for subsequent use. Prophylaxis with prednisolone does not appear to prevent hypersensitivity reactions to abacavir. Importantly, genetic susceptibility appears to be conferred by the HLA-B*5701 allele with a positive predictive value of > 70% and negative predictive value of 95%–98%. Genetic screening would be cost-effective in Caucasians, but not in African or Asian populations as their HLA-B*5701 allele frequency is < 1%.

10. Adverse Reactions to Chemotherapeutic Agents

A number of chemotherapeutic agents, including monoclonal antibodies, have been implicated in hypersensitivity reactions. Rapid desensitization to unrelated agents, including carboplatin, paclitaxel, and rituximab, has been reported. This 12-step protocol appeared to be successful in both IgE- and non–IgE-mediated reactions.

FOOD ALLERGY

A. Symptoms and Signs

A thorough medical history is crucial in identifying symptoms associated with potential food allergy; a history of a temporal...

</tbody>
</table>

Relationship between the ingestion of a suspected food and onset of a reaction—as well as the nature and duration of symptoms observed—is important in establishing the diagnosis. For all IgE-mediated reactions, reactions to foods occur within minutes and up to 2 hours after ingestion. For the non–IgE-mediated and mixed disorders, reactions can be delayed in onset for more than several hours, such as in food protein–induced enterocolitis, to possibly days later with onset of vomiting or an eczema flare after food exposure due to eosinophilic esophagitis or atopic dermatitis, respectively. At times, acute symptoms may occur, but the cause may not be obvious because of hidden food allergens. A symptom diary kept for 7–14 days may be helpful in establishing an association between ingestion of foods and symptoms and also provides a baseline observation for the pattern of symptom expression. It is important to record both the form in which the food was ingested and the foods ingested concurrently.

Hives, flushing, facial angioedema, and mouth or throat itching are common. In severe cases, angioedema of the tongue, uvula, pharynx, or upper airway can occur. Contact urticaria can occur without systemic symptoms in some children. Gastrointestinal symptoms include abdominal discomfort or pain, nausea, vomiting, and diarrhea. Children with food allergy may occasionally have isolated rhinoconjunctivitis or wheezing. Rarely, anaphylaxis to food may involve only cardiovascular collapse.

B. Laboratory Findings

Typically, fewer than 50% of histories of food allergy will be confirmed by blinded food challenge (although this percentage is much higher in food-induced anaphylaxis). Prick skin testing is useful to rule out a suspected food allergen, because the predictive value is high for a properly performed negative test with an extract of good quality (negative predictive accuracy of > 95%). In contrast, the predictive value for a positive test is approximately 50%. Serum food-specific IgE tests have lower specificity and positive predictive values. In contrast, food-specific IgE levels to milk, egg, peanut, and fish proteins have been established with the ImmunoCAP assay correlating with a greater than 95% chance of a clinical reaction, but values have not been established for other foods. A list of nonstandardized and unproven procedures for the diagnosis of food allergy, including the measurement of allergen-specific-IgG to foods, is provided in the Food Allergy Guidelines.

The double-blind, placebo-controlled food challenge is considered the gold standard for diagnosing food allergy, except in severe reactions. If there is high suspicion of possible allergic reactivity to a food with a negative skin test or an undetectable IgE level (or both), a food challenge may be necessary to confirm the presence or absence of allergy. Even when multiple food allergies are suspected, most patients will test positive to three or fewer foods on blinded challenge. Therefore, extensive elimination diets are almost never indicated, and an evaluation by an allergist is preferred before multiple foods are eliminated from the diet unnecessarily. Elimination without controlled challenge is a less desirable but at times more practical approach for suspected food allergy. Elimination diets and food challenges may also be the only tools for evaluation of suspected non–IgE-mediated food reactions.

Differential Diagnosis

Repeated vomiting in infancy may be due to pyloric stenosis or gastroesophageal reflux. With chronic gastrointestinal symptoms, enzyme deficiency (eg, lactase), cystic fibrosis, celiac disease, chronic intestinal infections, gastrointestinal malformations, and irritable bowel syndrome should be considered.

Treatment

Treatment consists of eliminating and avoiding foods that have been documented to cause allergic reactions. This involves educating the patient, parent, and caregivers regarding hidden food allergens, the necessity for reading labels, and the signs and symptoms of food allergy and its appropriate management (emergency action plan; a copy of this plan is provided in the Food Allergy Guidelines). New food labeling laws went into effect in January 2006 requiring simple terms to indicate the presence of the major food allergens listed previously (eg, milk instead of casein). Consultation with a dietitian familiar with food allergy may be helpful, especially when common foods such as milk, egg, peanut, soy, or wheat are involved. All patients with a history of IgE-mediated food allergy should carry self-injectable...
epinephrine (Auvi-Q or Epipen) and a fast-acting antihistamine, have an anaphylaxis action plan, and consider wearing medical identification jewelry. Clinical trials of oral and sublingual immunotherapy are currently under investigation as potential future treatments of food allergy. However, diets containing extensively heated (baked) milk and egg are potential alternative approaches to food oral immunotherapy and are changing the previous standard of strict avoidance diets for patients with food allergy.

Prognosis

The prognosis is good if the offending food can be identified and avoided. Unfortunately, accidental exposure to food allergens in severely allergic patients can result in death. Most children outgrow their food allergies to milk, egg, wheat, and soy but not to peanut or tree nuts (only 20% and 10% of children may outgrow peanut and tree nut allergy, respectively). The natural history of food allergy can be followed by measuring food-specific IgE levels and performing food challenges when indicated. Approximately 3%–4% of children will have food allergy as adults. Resources for food-allergic patients include the Food Allergy Research & Education at: (800) 929-4040; www.foodallergy.org; and the Consortium of Food Allergy Research: www.cofargroup.org.

INSECT ALLERGY

Allergic reactions to insects include symptoms of respiratory allergy as a result of inhalation of particulate matter of insect origin, local cutaneous reactions to insect bites, and anaphylactic reactions to stings. The latter are almost exclusively caused by Hymenoptera and result in approximately 40 deaths each year in the United States. The order Hymenoptera includes honeybees, yellow jackets, yellow hornets, white-faced hornets, wasps, and fire ants. Africanized honeybees, also known as killer bees, are a concern because of their aggressive behavior and excessive swarming, not because their venom is more toxic. Rarely, patients sensitized to reduviid bugs (also known as kissing bugs) may have episodes of nocturnal anaphylaxis. Lepidopterism refers to adverse effects secondary to contact with larval or adult butterflies and moths. Salivary gland antigens are responsible for immediate and delayed skin reactions in mosquito-sensitive patients.

Clinical Findings

A. Symptoms and Signs

Insect bites or stings can cause local or systemic reactions ranging from mild to fatal responses in susceptible persons. The frequency increases in the summer months and with outdoor exposure. Local cutaneous reactions include urticaria as well as papulovesicular eruptions and lesions that resemble delayed hypersensitivity reactions. Papular urticaria is almost always the result of insect bites, especially of mosquitoes, fleas, and bedbugs. Toxic systemic reactions consisting of gastrointestinal symptoms, headache, vertigo, syncope, convulsions, or fever can occur following multiple stings. These reactions result from histamine-like substances in the venom. In children with hypersensitivity to fire ant venom, sterile pustules occur at sting sites on a nonimmunologic basis due to the inherent toxicity of piperidine alkaloids in the venom. Mild systemic reactions include itching, flushing, and urticaria. Severe systemic reactions may include dyspnea, wheezing, chest tightness, hoarseness, fullness in the throat, hypotension, loss of consciousness, incontinence, nausea, vomiting, and abdominal pain. Delayed systemic reactions occur from 2 hours to 3 weeks following the sting and include serum sickness, peripheral neuritis, allergic vasculitis, and coagulation defects.

B. Laboratory Findings

Skin testing is indicated for children with systemic reactions.Venoms of honeybee, yellow jacket, yellow hornet, white-faced hornet, and wasp are available for skin testing and treatment. Fire ant venom is not yet commercially available, but an extract made from fire ant bodies appears adequate to establish the presence of IgE antibodies to fire ant venom. Of note, venom skin test results can be negative in patients with systemic allergic reactions, especially in the first few weeks after a sting, and the tests may need to be repeated. The presence of a positive skin test denotes prior sensitization but does not predict whether a reaction will occur with the patient’s next sting, nor does it differentiate between local and systemic reactions. It is common for children who have had an allergic reaction to have positive skin tests to more than one venom. This might reflect sensitization from prior stings that did not result in an allergic reaction or cross-reactivity between closely related venoms. In vitro testing (compared with skin testing) has not substantially improved the ability to predict anaphylaxis. With venom RAST, there
is a 15%–20% incidence of both false-positive and false-negative results. Tests for mosquito saliva antigens or other insect allergy are not commercially available.

**Complications**

Secondary infection can complicate allergic reactions to insect bites or stings. Serum sickness, nephrotic syndrome, vasculitis, neuritis, and encephalopathy may be seen as late sequelae of reactions to stinging insects.

**Treatment**

For cutaneous reactions caused by biting insects, symptomatic therapy includes cold compresses, antipruritics (including antihistamines), and occasionally potent topical corticosteroids. Treatment of stings includes careful removal of the stinger, if present, by flicking it away from the wound and not by grasping in order to prevent further envenomation. Topical application of monosodium glutamate, baking soda, or vinegar compresses is of questionable efficacy. Local reactions can be treated with ice, elevation of the affected extremity, oral antihistamines, and NSAIDs as well as potent topical corticosteroids. Large local reactions, in which swelling extends beyond two joints or an extremity, may require a short course of oral corticosteroids. Anaphylactic reactions following Hymenoptera stings should be managed essentially the same as anaphylaxis (see section on Anaphylaxis). Children who have had severe or anaphylactic reactions to Hymenoptera stings—or their parents and caregivers—should be instructed in the use of epinephrine. Patients at risk for anaphylaxis from an insect sting should also wear a medical alert bracelet indicating their allergy. Children at risk from insect stings should avoid wearing bright-colored clothing and perfumes when outdoors and should wear long pants and shoes when walking in the grass. Patients who experience severe systemic reactions and have a positive skin test should receive venom immunotherapy. Immunotherapy is not indicated for children with only urticarial or local reactions.

**Prognosis**

Children generally have milder reactions than adults after insect stings, and fatal reactions are extremely rare. Patients aged 3–16 years with reactions limited to the skin, such as urticaria and angioedema, appear to be at low risk for more severe reactions with subsequent stings.

Antimicrobial Therapy

John W. Ogle, MD

PRINCIPLES OF ANTIMICROBIAL THERAPY

Antimicrobial therapy of infections is arguably the most important scientific development of 20th-century medicine. It contributes significantly to the quality of life of many people and reduces the morbidity and mortality due to infectious disease. The remarkable success of antimicrobial therapy has been achieved with comparatively little toxicity and expense. The relative ease of administration and the widespread availability of these drugs have led many to adopt a philosophy of broad-spectrum empiric antimicrobial therapy for many common infections.

Unfortunately this era of cheap, safe, and reliable therapy is being limited by the increasing frequency of antimicrobial resistance in previously susceptible microorganisms. The problem of antimicrobial resistance is not new—resistance was recognized for sulfonamides and penicillins shortly after their introduction. What is new is the worldwide dissemination of resistant clones of microorganisms, such as *Streptococcus pneumoniae* and *Staphylococcus aureus*, which are more virulent and commonly cause serious infections, not only among hospitalized patients, but also among outpatients.

Until recently the recognition of new resistant clones was balanced by the promise of newer and more potent antimicrobial agents. Today, because fewer new agents are under development, clinicians are beginning to encounter limitations in their ability to treat some serious bacterial infections. Many factors contribute to the selection of resistant clones. Our success in treating chronic diseases and immune-compromising conditions, which has resulted in additional years of life for patients, has increased opportunities for selection of resistant strains in inpatient units and chronic care facilities. Overuse of antimicrobial agents also contributes to the selection of resistant strains. Examples include antimicrobial treatment of mildly ill patients with self-limited conditions, such as viral infections, and administration of broad-spectrum antimicrobials to patients whose conditions could be treated with narrow-spectrum agents. Similarly, failure to document infection with cultures obtained prior to starting therapy limits our willingness to stop or narrow the spectrum of antimicrobials. Insufficient research has been conducted to determine the optimal duration of therapy for many infections, with the result that we probably often treat longer than is necessary. Prophylactic strategies, as used for prevention of recurrent otitis media or urinary tract infection (UTI), create a selection pressure for antibiotic resistance.

The decision-making process for choosing an appropriate antimicrobial agent is summarized in Table 39–1. Accurate clinical diagnosis is based on the history, physical examination, and initial laboratory tests. The clinical diagnosis then leads to a consideration of the organisms most commonly associated with the clinical condition, the usual pattern of antimicrobial susceptibility of these organisms, and past experience with successful treatment regimens.

Data regarding US outpatient pediatric antimicrobial prescriptions show a decreased number of antimicrobial prescriptions in 2010 compared to 2002. The most frequently prescribed antimicrobials are amoxicillin, azithromycin, amoxicillin-clavulanate, and cefdinir. However, neither azithromycin nor cefdinir is recommended as first line agent for the most common pediatric conditions, suggesting that these agents may be overprescribed.

Cultures should be obtained in potentially serious infections. Empiric antimicrobial therapy may be initiated and then modified according to the patient’s response and the culture results. Often several equally safe and efficacious antimicrobials are available. In this circumstance, the relative cost and ease of administration of these choices should be considered.

Other important considerations include the patient’s age, immune status, and exposure history. Neonates and young infants may present with nonspecific signs of infection,
making the differentiation of serious disease from mild illness difficult. In older children, clinical diagnosis is more precise, which may permit therapy to be avoided or allow use of a narrower-spectrum antibiotic. Immune deficiency may increase the number and types of potential infecting organisms that need to be considered, including organisms that are usually avirulent, but in the altered host may cause serious infections that are difficult to treat. An abnormal immune response may also diminish the severity of the clinical signs and symptoms of infection, leading to underestimation of the severity of illness. The exposure history may suggest the greater likelihood of certain types of infecting organisms. This history includes exposures from family members, classmates, and day care environments, and exposure to unusual organisms by virtue of travel, diet, or contact with animals.

Final important considerations are the pace and seriousness of the illness. A rapidly progressive and severe illness should be treated initially with broad-spectrum antimicrobials until a specific etiologic diagnosis is made. A mildly ill outpatient should receive treatment preferentially with narrow-spectrum antimicrobials.

Antimicrobial susceptibility, antimicrobial families, and dosing recommendations are listed in Tables 39–2 to 39–6.

### ANTIMICROBIAL SUSCEPTIBILITY TESTING

Cultures and other diagnostic material must be obtained prior to initiating antimicrobial therapy—especially when the patient has a serious infection, initial attempts at therapy have failed, a patient has an unusual exposure, or multiagent therapy is anticipated. Whenever cultures identify the causative organism, therapy can be narrowed or optimized according to susceptibility results. Antimicrobial susceptibility testing should be done in a laboratory using carefully defined procedures (as defined by the Clinical and Laboratory Standards Institute).

There are several ways to test antimicrobial susceptibility. Identification of an antibiotic-destroying enzyme (eg, β-lactamase) implies resistance to β-lactam–containing antimicrobial agents. Tube or microtiter broth dilution techniques can be used to determine the minimum inhibitory concentration (MIC) of an antibiotic, which is the amount of antibiotic (in mcg/mL) necessary to inhibit the organism under specific laboratory conditions. Disk susceptibility testing (also performed under carefully controlled conditions) yields similar results. The E-test is a standardized test for some organisms that correlates well with MICs. Clinical laboratories usually define antimicrobial susceptibility (susceptible, intermediate, and resistant) in relation to levels of the test antibiotic achievable in the blood or another body fluid (cerebrospinal fluid [CSF] or urine).

Organisms are usually considered susceptible to an antibiotic if the MIC of the antibiotic for the organism is significantly lower than levels of that agent achieved in the blood using appropriate parenteral dosages. This assumption of susceptibility should be reconsidered whenever the patient has a focus of infection (eg, meningitis, osteomyelitis, or abscesses) in which poor antibiotic penetration might occur, because the levels of antibiotic in such areas might be lower than the MIC. Conversely, although certain organisms may be reported to be resistant to an antibiotic because sufficiently high blood concentrations cannot be achieved, urine concentrations may be much higher. If so, a UTI might respond to an antibiotic that would not be adequate for treatment of septicemia.

Thus, antimicrobial susceptibility testing, although a very important part of therapeutic decision making, reflects assumptions that the clinician must understand, especially for serious infections. Ultimately the true test of the efficacy of therapy is patient response. Patients who do not respond to seemingly appropriate therapy may require reassessment, including reconsidering the diagnosis, reculturing, and repeat susceptibility testing, to determine whether resistant strains have evolved or superinfection with a resistant organism is present. Antimicrobial therapy cannot be expected to

<sup>a</sup>In alphabetical order. Selection depends on patient’s age, diagnosis, site of infection, severity of illness, antimicrobial susceptibility of suspected organism, and drug risk.

<sup>b</sup>Species-dependent.

<sup>c</sup>Not FDA-approved for use in children.

<sup>d</sup>Refer to first (I), second (II)<sup>–</sup>, or third (III)<sup>–</sup> generation cephalosporins.

<sup>e</sup>Includes ciprofloxacin, levofloxacin, lomefloxacin, norfloxacin, ofloxacin, moxifloxacin, gatifloxacin, gemifloxacin.

<sup>f</sup>Includes *E coli, Klebsiella* spp, *Enterobacter* spp, and others; antimicrobial susceptibilities should always be measured.

<sup>g</sup>Amikacin, gentamicin, kanamycin, tobramycin.

<sup>h</sup>Also applies to amoxicillin and related compounds.

<sup>i</sup>Cloxacillin, dicloxacillin, methicillin, nafcillin, oxacillin.

<sup>j</sup>Only if the coagulase-negative *Staphylococcus* is also methicillin- or oxacillin-sensitive.

<sup>k</sup>Includes levofloxacin, lomefloxacin, moxifloxacin, gatifloxacin, gemifloxacin.

<sup>l</sup>Because of increasing frequency of *S pneumoniae* strains resistant to penicillin and cephalosporins, presumptive therapy for severe infections (eg, meningitis) should include vancomycin until susceptibility studies are available.

<sup>m</sup>Influenza A only. Resistance is common, currently recommended in the United States only for seasonal H1N1 strains.

<sup>n</sup>FDA-approved for therapy of respiratory syncytial virus by aerosol, but clinical studies show variable efficacy.

<sup>o</sup>Used to treat infections with acyclovir-resistant virus.

<sup>p</sup>Ophthalmic preparation.

<sup>a</sup>Not all strains susceptible; always obtain antimicrobial susceptibility tests on significant isolates.

<sup>b</sup>MRSA = methicillin-resistant *S aureus*.

<sup>c</sup>Fluoroquinolones are used with caution in children.

<sup>d</sup>Dose-dependent in children younger than age 9 years.

Cure some infections unless additional supportive treatment (usually surgical) is undertaken.

### ALTERATION OF DOSE & MEASUREMENT OF BLOOD LEVELS

Certain antimicrobial agents have not been approved (and often not tested) for use in newborns. For those that have been approved, it is important to recognize that both dose and frequency of administration may need to be altered (see Tables 39–4 and 39–5), especially in young (7 days or younger) or low-birth-weight neonates (< 2000 g).

Antimicrobial agents are excreted or metabolized through various physiologic mechanisms (eg, renal, hepatic). It is important to consider these routes of excretion and alter the antimicrobial dosage appropriately in any patient with some degree of organ dysfunction. (See Chapter 24.) As indicated in Table 39–4, an assessment of renal or hepatic function may routinely be necessary for patients receiving certain drugs (eg, renal function for aminoglycosides, hepatic function...

aNot including some newly released drugs, ones not recommended for use in children, or ones not widely used.
bAlways consult package insert for complete prescribing information. Dosage may differ for alternative routes, newborns (see Table 39–6), or patients with liver or renal failure (see Adjustment column) and may not be recommended for use in pregnant women or newborns. Maximum dosage may be indicated only in severe infections.
cMode of excretion (R = renal, H = hepatic) of antimicrobial agent should be assessed at the onset of therapy and dosage modified or levels determined as indicated in package insert.
dSuggested levels to reduce toxicity.
eAminoglycosides are sometimes given as a once-daily dose. See text.
fUse with caution in children younger than age 9 years because of tooth staining with repeated doses.
gTarget peak and trough vancomycin levels are not well correlated with either toxicity or outcome. Measure selectively in meningitis, impaired or changing renal function, or altered volume of distribution. Higher trough levels sometimes indicated for difficult to treat infections.

*a* Penicillin dosages are in Units/kg/d. Other preparations (eg, benzathine penicillin) may be given IM. See specific diseases for dosage.

*b* Vancomycin dosing is dependent on gestational age and serum creatinine with monitoring of levels. 10–15 mg/kg/dose every 12–48 hours.

for erythromycin or clindamycin); otherwise, harmful drug levels may accumulate. In some circumstances a patient may be receiving multiple drugs where the drug interactions are unknown. If significant organ dysfunction is present, drug clearance may be delayed and dosage modification may be necessary (see detailed descriptions in individual drug information packets), and measurement of drug levels may be indicated.

Serum levels of drugs posing a high risk of toxicity (eg, aminoglycosides) are ordinarily measured. Measurement of other drugs (eg, vancomycin) may be useful in selected circumstances (see the following discussion). For certain serious bacterial infections (eg, bacterial endocarditis), measurement of the serum concentration of an antimicrobial may be important to determine optimal therapy.

Certain drug interactions may require modification of drug dosage or other therapeutic alterations. For example, rifampin stimulates the metabolism of warfarin, progesterone, prednisone, and anticonvulsants by stimulating the cytochrome P450 (CYP450) metabolic pathway. Dosage adjustments or alternative medications may be necessary to avoid significant adverse events. Another common example is erythromycin, which may inhibit the metabolism of theophylline, resulting in toxic theophylline levels. Although many drug interactions are known and well documented, it may be difficult to predict interactions that result from a combination of four, five, or more different medications. A high level of suspicion regarding adverse clinical events should be maintained.

### The Use of New Antimicrobial Agents

New antibiotics are introduced frequently, often with claims about unique features that distinguish these usually more expensive products from existing compounds. Often these drugs share many properties with existing drugs. The role that any new antimicrobial will play can only be determined over time, during which new or previously unrecognized side effects might be described and the clinical efficacy established. Clinical trials may not be confirmed in the larger number of patients subsequently treated in practice. Because this may take many years, a conservative approach to using new antibiotics seems fitting, especially because their costs are often higher, and appropriate antimicrobial choices for...
most common infections already exist. It is appropriate to ask if a new antimicrobial has been proved to be as effective as (or more effective than) the current drug of choice, and whether its side effects are comparable (or less common) and its cost reasonable. The withdrawal of moxalactam and trovafloxacin due to unexpected serious side effects, which were not anticipated despite extensive premarket testing, highlight the caution necessary before using new antimicrobials. The heavy marketing of new cephalosporins and fluoroquinolones, which are very similar to existing drugs, is typical of the difficulty in evaluating antimicrobials.

The development of new antibiotics is important as a response to the emergence of resistant organisms and for treatment of infections that are clinically difficult to treat (eg, viruses, fungi, and some resistant bacteria). Fortunately, these infections are either rare or (usually) self-limited in immunocompetent hosts.

**PROPHYLACTIC ANTIMICROBIAL AGENTS**

Antimicrobials can be used to decrease the incidence of postoperative infections (Table 39–7). A dose of an antimicrobial given 30 minutes to 2 hours prior to surgery can reduce postoperative wound infection. The goal is to achieve high levels in the serum at the time of incision and by this means—to along with good surgical technique—to minimize viable bacterial contamination of the wound. During a lengthy procedure, a second dose may be given. No evidence exists that multiple subsequent doses of antimicrobials confer additional benefit. The antimicrobial(s) used for prophylaxis are directed toward the flora that most commonly cause postoperative infection at a given anatomic site. Gram-positive cocci, such as *S aureus* that colonize the skin, are usually targeted, and a first-generation cephalosporin (eg, cefazolin) is a cost-effective choice. Third-generation cephalosporins and other broad-spectrum agents are more expensive and offer less benefit because they are less active than cefazolin against *S aureus*. Cefoxitin and cefotetan, which have activity against anaerobic bacteria, are useful for procedures, such as colorectal surgery, although cefazolin has been effective for most gynecologic patients. In colorectal surgery, orally administered antimicrobials such as neomycin and erythromycin may be as effective as parenteral antimicrobials.

In hospitals where the predominant *S aureus* strains are methicillin resistant or in cases where the patient is allergic to penicillin and cephalosporins, vancomycin can be considered. However, prophylactic vancomycin has caused hypotension at the time of induction of general anesthesia. Frequent use of vancomycin as a prophylactic antimicrobial will contribute to the development of vancomycin-resistant strains such as *Enterococcus faecalis*. For these reasons, vancomycin should generally not be used for prophylaxis, although it might prove useful for individual patients at extremely high risk.

Endocarditis prophylaxis is recommended for certain dental procedures in high-risk cardiac patients. Patients with prosthetic cardiac valves or prosthetic cardiac material during the 6 months following the procedure, unrepaired cyanotic heart disease, children with prior endocarditis, and children with other prosthetic patches, which inhibit endothelialization, should receive prophylaxis. Dental procedures that would trigger prophylaxis are those that involve manipulation of gingival tissue, periapical tissues. Patients with indwelling venous catheters undergoing similar extensive dental procedures should receive prophylaxis. Prophylaxis is not recommended for routine cleanings or orthodontic applications. Prophylaxis is not recommended for other gastrointestinal or genitourinary procedures.

Prophylaxis against infection with group A streptococci reduces the recurrence rate for acute rheumatic fever. Postexposure prophylaxis is given after exposure to pertussis, *Haemophilus influenzae* type b (Hib) infection (depending on age), meningococcus, gonococcus, tuberculosis (household exposure), plague, aerosolized tularemia or

*aAminoglycoside dosing in neonates requires careful attention to changes in renal function and changes in the volume of distribution. For infant younger than 1200 g smaller doses may be needed.*
anthrax, and other high-risk infections. Family or close contacts of patients with severe invasive streptococcal disease may benefit from prophylaxis. Silver nitrate, erythromycin, povidone-iodine, and tetracycline are used in ophthalmic preparations for prevention of gonococcal ophthalmia neonatorum. Children with asplenia or sickle cell disease receive prophylactic penicillin to protect against overwhelming *S. pneumoniae* sepsis, usually started immediately with the onset of fever.

Prophylactic antimicrobials are sometimes used for some children at high risk for recurrent UTI, but the rate of infection has not been proven to decrease.

Chemoprophylaxis of children at high risk for influenza but not immunized against influenza should be considered, including some immunocompromised children and unimmunized caregivers of at-risk children and children at high risk for 2 weeks after immunization. Oseltamivir or Zanamivir would be used as each is usually active against influenza A and B.

**INITIAL EMPIRIC ANTIMICROBIAL CHOICES FOR SELECTED CONDITIONS**

General recommendations for specific conditions are as follows. A specific selection depends on the patient’s age, diagnosis, site of infection, severity of illness, antimicrobial susceptibility of bacterial isolates, and history of drug allergy. Always consult the package insert for detailed prescribing information. Tables 39–2 to 39–6 include further information.

**Neonatal Sepsis & Meningitis**

The newborn with sepsis may have signs of focal infection, such as pneumonia or respiratory distress syndrome, or may have subtle nonfocal signs. Group B streptococci, *Escherichia coli*, and other gram-negative rods are commonly encountered. *Listeria monocytogenes* is now uncommon in many nurseries, but a recent nationwide outbreak demonstrates the pathogenic potential of this organism. Ampicillin and gentamicin (or another aminoglycoside) are preferred. If meningitis is present, many clinicians substitute a third-generation cephalosporin for the aminoglycoside. *S. pneumoniae* is an uncommon cause of meningitis in neonates. However, if the Gram stain shows gram-positive cocci suggesting *S. pneumoniae*, substitution of vancomycin for ampicillin should be considered. In the newborn with cellulitis, *S. aureus* including methicillin-resistant *S. aureus* (MRSA) and group A streptococci are additional considerations. Nafcillin, oxacillin, or a first-generation cephalosporin is usually added. Vancomycin is added if MRSA is common in the geographic area. Ophthalmia is often polymicrobial, and *Enterococcus* species, gram-negative aerobes, and anaerobes may be causative. Clindamycin, ampicillin, and an aminoglycoside or cefotaxime cover the most likely organisms; early surgical intervention is indicated.

**Sepsis in an Infant**

*S. pneumoniae* and *Neisseria meningitidis* are most commonly encountered in infants. Hib infection may occur in unimmunized children. A third-generation cephalosporin is appropriate. Intermediate-level penicillin and cephalosporin resistance in *S. pneumoniae* usually do not cause therapy to fail unless meningitis or another difficult-to-treat infection, such as endocarditis or osteomyelitis, is present.

Occult bacteremia may be encountered in young infants with high fever. Prior to immunization with vaccines effective against Hib, persistent bacteremia and complications including meningitis were seen in approximately 50% of children infected with occult Hib bacteremia. With widespread use of Hib vaccine, Hib is a very uncommon cause of occult bacteremia in young children with fever. Similarly, prior to the introduction of the conjugate pneumococcal vaccine, *S. pneumoniae* bacteremia was demonstrated in 3%–5% of infants aged 3–36 months with fever of 39°C or greater, no identified source for fever on examination, and white blood cell count (WBC) of 15,000/mm³. The risk of bacteremia was 6%–10% in younger children with fever greater than 40°C and WBC of 20,000/mm³ or higher. The risk of developing meningitis due to persistent *S. pneumoniae* is estimated at 3% of those who are known to be bacteremic. The risk of *S. pneumoniae* bacteremia and its complications is significantly reduced in children immunized with the conjugate pneumococcal vaccines. In clinical trials and subsequent national surveillance for the incidence of disease, the 7-valent pneumococcal vaccine reduced the incidence of invasive pneumococcal diseases by approximately 90%. Studies are underway with the newer 13 valent pneumococcal vaccines. Observation without antimicrobials, but with appropriate plans for follow-up examinations, is appropriate for most febrile young children who are fully immunized.

**Nosocomial Sepsis**

Many bacterial pathogens can cause infection in hospitalized patients. Recent local experience is usually the best guide to etiologic diagnosis. For example, some intensive care units experience frequent infections due to *Enterobacter cloacae*, whereas in other units *Klebsiella pneumoniae* is the most common nosocomial isolate. Initial therapy should include antibiotics effective for MRSA and resistant *Pseudomonas aeruginosa* if these are frequent isolates. *E. faecalis* is a common cause of nosocomial bacteremia in patients with central catheters, particularly in units where cephalosporins are heavily used. Coagulase-negative staphylococci are commonly isolated from patients with indwelling central catheters. In seriously ill patients, when the local experience suggests that *Enterococcus* species or coagulase-negative staphylococci are common, the initial regimen should include vancomycin.
Because *Enterococcus* species and coagulate-negative staphylococci commonly cause fever without significant morbidity or mortality, initial regimens without vancomycin are appropriate, with adjustment of treatment after susceptibility is known. If *P. aeruginosa* or other resistant gram-negative rods are common, ceftazidime or cefepime should be included in initial therapy. *Candida* is a common isolate from blood cultures from immunocompromised or seriously ill patients in the intensive care unit. Empiric antifungal therapy is initiated in some high-risk patients.

**Meningitis**

Bacterial meningitis in neonates is usually caused by infection with group B streptococci, *E. coli*, other gram-negative rods, or *L. monocytogenes*. A combination of ampicillin and a third-generation cephalosporin is started initially. In an infant or older child, *S. pneumoniae* or *N. meningitidis* are the most common isolates. Hib is uncommon now because of widespread immunization. Increasingly, *S. pneumoniae* with resistance to a third-generation cephalosporin (MIC > 2 mcg/mL) may occur in 3%–5% of isolates.

In bacterial meningitis, peak CSF antimicrobial concentrations 10 or more times greater than the MIC of the organism are desirable, but this may be difficult to achieve if organisms are resistant. The therapeutic problem is complicated if dexamethasone, which reduces the entry of some antimicrobials into the CSF, is also given. Thus, initial therapy of bacterial meningitis in an older child should include vancomycin and a third-generation cephalosporin. Alternatively, meropenem has also been successful. A lumbar puncture should be considered 24–48 hours after the start of therapy to assess the sterility of the CSF. Rifampin should be added if the Gram stain or cultures of CSF are positive on repeated lumbar puncture, if the child fails to improve, or if an organism with a very high MIC to ceftriaxone is isolated. The optimal therapy of highly resistant *S. pneumoniae* meningitis is not well established.

Meningitis in a child with a ventriculoperitoneal shunt is most commonly caused by coagulate-negative staphylococci, many of which are methicillin-resistant, or *Corynebacterium* species, which are resistant to many antimicrobials. In many of these patients who are not seriously ill, therapy should be postponed while awaiting the appropriate shunt fluid for Gram stain and culture. Seriously ill patients should initially be given vancomycin and a third-generation cephalosporin, because *S. aureus* and gram-negative rods are also possible and can cause serious infection.

**Urinary Tract Infection**

*E. coli* is the most common isolate from the urinary tract. Outpatients with symptoms of lower urinary tract disease or with mild illness can be given ampicillin, cephalaxin, or trimethoprim-sulfamethoxazole (TMP-SMX). Local experience and resistance rates should guide initial therapy. In selected patients with pyelonephritis, outpatient therapy is effective using parenteral aminoglycosides or ceftriaxone once per day. Oral cefixime and amoxicillin-clavulanate can be used in place of ceftriaxone for outpatient therapy. Ciprofloxacin has been approved by the US Food and Drug Administration for therapy of urinary tract infection (UTI) in children older than 1 year, but it should be reserved for complicated cases. For hospitalized patients with UTI and suspected bacteremia, ampicillin and gentamicin or a third-generation cephalosporin is appropriate. Gram stain should be used to guide the initial choice. For patients with known or suspected resistant organisms, such as *P. aeruginosa*, or for patients with urosepsis, an aminoglycoside and ceftazidime, cefepime, or ticarcillin may be started. Unit-specific data on typical bacterial species and their patterns of susceptibility should guide the antimicrobial choice for nosocomial UTIs.

**Bacterial Pneumonia**

Bacterial pneumonia in newborns generally should be treated with the same antimicrobial choices as sepsis. Infants and older children are frequently infected with *S. pneumoniae*. Ampicillin and amoxicillin are effective in most patients eligible for outpatient therapy.

Previously healthy children admitted to the hospital with uncomplicated pneumonia can be treated successfully with amoxicillin, ampicillin, or penicillin.

Children with inadequate immunization, children with high-level pneumococcal resistance (penicillin MIC ≥ 4.0 mg/mL), and children who are critically ill may benefit from a third-generation cephalosporin.

Children with culture-positive parapneumonic effusions should be treated based on the culture and susceptibility report. Children with small or culture-negative parapneumonic effusions should be treated based on the severity of illness.

A rapidly progressive pneumonia, with pneumatoceles or large empyema, may be due to MRSA or group A streptococci, Hib, or another gram-negative rod. Vancomycin should be used in addition to a third-generation cephalosporin in these instances.

Children aged 6 years and older more frequently have infection with *Mycoplasma pneumoniae* or *Chlamydia pneumoniae*. Azithromycin is usually preferred for initial empiric therapy.

**Skin & Soft Tissue Infections**

*S. aureus* and *Streptococcus pyogenes* are the most common causes of skin and soft tissue infections (SSTIs) in children.
Community-acquired MRSA infections are common in many communities and complicate clinical decision making. Culture and susceptibility testing of abscesses, cellulitis, and more serious SSTIs is very important for optimal clinical management. Children with cellulitis more commonly have infection with group A streptococci, and empiric outpatient therapy with cephalaxin or dicloxacillin is preferred. Children with small (<5 cm) abscesses usually are effectively treated with incision and drainage without an antimicrobial. Outpatient therapy of large (>5 cm) abscesses includes incision and drainage and empiric clindamycin or TMP-SMX, depending on local susceptibility patterns. However, in many communities, 50% or more of MRSA isolates are also resistant to clindamycin, fluoroquinolones, and erythromycin. Knowledge of the local resistance pattern of community-acquired MRSA is helpful in choosing initial antimicrobial therapy. Adequate cultures, the thoroughness of drainage procedures, and careful outpatient follow-up are needed to ensure optimal outcomes. Group A streptococcal infections are not adequately treated with TMP-SMX.

Penicillinase-Resistant Penicillins

S aureus is usually resistant to penicillin and amoxicillin owing to penicillinase production. Nafcillin, oxacillin, methicillin, and first- and second-generation cephalosporins are stable to penicillinase and are usually equivalent for intravenous therapy. Methicillin is associated with more frequent interstitial nephritis. Oxacillin and methicillin are renally excreted, whereas nafcillin is excreted through the biliary tract. These properties are occasionally considered in children with renal or liver failure. Cost should usually be the deciding factor for choosing an agent. Often both S aureus and S pyogenes are suspected initially (eg, in cellulitis or postoperative wound infections). The penicillinase-resistant penicillins (PRPs) and first- and second-generation cephalosporins are efficacious for most streptococcal infections, although penicillin remains the drug of choice.

MRSA is an increasingly common and serious community-acquired infection in children and may cause nosocomial infection. MRSA infections are also resistant to all of the PRPs and cephalosporins. Vancomycin is effective against MRSA and coagulase-negative staphylococci. S aureus infections range in severity from minor infections treated on an outpatient basis to life-threatening infections. Severe infections due to MRSA are a serious concern in many communities. It is important to culture and determine antimicrobial susceptibility of suspected S aureus infections. In communities with frequent MRSA infections in children, initial therapy of seriously ill children should include vancomycin. MRSA may also be resistant to macrolides and clindamycin by alteration in the bacterial 23S-ribosomal RNA. Many strains reported as clindamycin-susceptible and erythromycin-resistant are truly resistant to clindamycin. This inducible resistance to clindamycin may be detected in erythromycin-resistant MRSA that demonstrates a D-zone in disk susceptibility testing to clindamycin. Community-acquired MRSA is more likely to be susceptible to TMP-SMX, clindamycin, and tetracyclines than hospital-acquired infections.

For outpatient therapy, cloxacillin, dicloxacillin, and first- or second-generation cephalosporins are usually equally effective for infections due to susceptible S aureus. Cost may determine the choice between drugs.

Anti-Pseudomonas Penicillins

Ticarcillin, mezlocillin, and piperacillin are active intravenously against streptococci, ampicillin-susceptible enterococci, H influenzae, gram-negative rods (including more resistant gram-negative rods such as Enterobacter, Proteus, and P aeruginosa), and gram-negative anaerobes such as Bacteroides fragilis. P aeruginosa is inherently resistant to most antimicrobials, and high levels of these drugs are

---

*Decisions for prophylaxis must take a number of factors into account, including the evidence for efficacy of therapy, the degree of the exposure to an infecting agent, the risk and consequences of infection, the susceptibility of the infecting agent to antimicrobials, and the patient’s ability to tolerate and comply with the antimicrobial agent. See individual chapters for discussion.*

*Prophylaxis provided to family if contacts include unimmunized or partially immunized children younger than age 4 years. Some experts provide prophylaxis in day care settings after one case and some after two cases of Hib infection.*

*Alternative regimens may be used, depending on the site of surgery and the degree of contamination. Vancomycin may be used when the patient is known to be colonized with MRSA or if MRSA is a common postoperative infection.*

*Pneumocystis jiroveci – (HIV, some immunocompromised patients) often require combination therapy due to drug resistance.*

*Oral prophylaxis may be indicated in some patients. Alternative regimens indicated for penicillin-allergic patients. See discussion in chapter.*

*Prophylaxis not well established. Carefully assess risk on a case-by-case basis.*

*Usualy not indicated for children younger than age 9 years because of tooth staining with repeated doses.*

---

usually required. The combination of ticarcillin or piperacillin and an aminoglycoside is synergistic against *P aeruginosa* and many other enteric gram-negative rods. Ticarcillin in a fixed combination with clavulanic acid has activity against β-lactamase–producing strains of *Klebsiella*, *S aureus*, and *Bacteroides*. Piperacillin is more active in vitro against many gram-negative enteric infections and may be advantageous in some circumstances, but it is not approved in children. Piperacillin-tazobactam is another combination antimicrobial and β-lactamase inhibitor that has enhanced activity against many β-lactamase producers.

Antipseudomonal penicillins cause the same toxicities as penicillin and therefore are usually very safe. Carbenicillin, ticarcillin, and piperacillin contain large amounts of sodium,
which may cause problems for some patients with cardiac or renal disease.

GLYCOPEPTIDE AGENTS

Vancomycin and teicoplanin are glycopeptide antimicrobial agents active against the cell wall of gram-positive organisms. Only vancomycin is licensed in the United States. Vancomycin is useful for parenteral therapy of resistant gram-positive cocci such as penicillin- and cephalosporin-resistant *S. pneumoniae*, MRSA, methicillin-resistant coagulase-negative staphylococci, and ampicillin-resistant enterococci. Vancomycin is also used orally for therapy of colitis due to *Clostridium difficile*, although it should not be used as the drug of first choice.

The empiric use of vancomycin has increased tremendously over the last decade. As a result, vancomycin-resistant enterococci (VRE) and coagulase-negative staphylococci have become problems, particularly in inpatient units, intensive care units, and oncology wards. *S. aureus* with increased MICs to vancomycin has been reported in the United States and Japan. This resistance is of concern because of the inherent virulence of many *S. aureus* strains. Vancomycin use should be monitored carefully in hospitals and their intensive care units. It should not be used empirically when an infection is mild or when other antimicrobial agents are likely to be effective. Vancomycin should be stopped promptly if infection is found to be due to organisms susceptible to other antimicrobials.

Rapid infusion of vancomycin is associated with the “red man syndrome,” characterized by diffuse red flushing, at times pruritus, and occasionally tachycardia and hypotension. As a result, vancomycin is infused slowly over 1 hour or longer in some cases. Diphenhydramine or hydrocortisone (or both) may also be used as premedication.

Measurement of peak-and-trough serum vancomycin concentrations is not necessary in most clinical situations, because the levels achieved with standard dosing are usually predictable and nontoxic. Measurement of serum concentrations is helpful in patients with abnormal or unpredictable renal function; in those with altered volume of distribution, as occurs in nephrotic syndrome or shock; and in those receiving higher-dose therapy (eg, for meningitis or other difficult-to-treat infections). For patients receiving antimicrobials for weeks to months, weekly monitoring of clinical signs and symptoms and of urinalysis, creatinine, and complete blood count will allow detection of toxicity.

OXAZOLIDINONES

Linezolid is the first drug in this class of antimicrobials which have a distinct new mechanism of action; they bind to the 50s-ribosomal RNA subunit and prevent initiation of protein synthesis. Because of this unique mechanism, there is no cross-resistance with other classes of antimicrobials. The in vitro development of resistance has also been uncommon.

Linezolid is active against aerobic gram-positive organisms, including streptococci, staphylococci, enterococci, and pneumococci. Because linezolid is active against gram-positive organisms resistant to other antimicrobials (eg, MRSA, methicillin-resistant coagulase-negative staphylococci, VRE, and penicillin-resistant *S. pneumoniae*), it is useful for these difficult-to-treat infections.

Linezolid is safe and well tolerated in children. Gastrointestinal symptoms are the most commonly encountered side effect. Neutropenia and thrombocytopenia have been reported, and linezolid should therefore be used with monitoring in patients at increased risk for these problems or in patients receiving therapy for 2 weeks or longer. Linezolid is an inhibitor of monoamine oxidase (MAO) and should not be used in patients taking MAO inhibitors, or in patients taking phenylpropanolamine or pseudoephedrine.

Linezolid should be used only for infections due to a proven gram-positive pathogen that is known or strongly suspected to be resistant to other available agents.

QUINUPRISTIN-DALFOPRISTIN

Quinupristin and dalfopristin are two antimicrobials of the streptogramin class, which individually are bacteriostatic, but in combination are synergistic and bacteriocidal. These drugs are combined in a fixed ratio of 70:30, known as Synercid. Streptogramins inhibit protein synthesis by binding to the 50s-ribosomal subunit. The streptogramins were discovered many years ago, but interest has increased only recently due to the activity of these agents against some very difficult-to-treat gram-positive infections.

The quinupristin-dalfopristin combination has activity against staphylococci, streptococci, pneumococci, and some enterococci. Quinupristin-dalfopristin is primarily indicated for serious infections due to vancomycin-resistant *Enterococcus faecium* and MRSA. Quinupristin-dalfopristin is not active against *E. faecalis* and, therefore, differentiation of these strains from *E. faecium* is important prior to initiating therapy.

Quinupristin-dalfopristin is not approved for therapy in children younger than 12 years. Nonetheless, therapy has been initiated in some pediatric patients seriously ill with difficult-to-treat infections due to resistant organisms.

Arthralgias and myalgias have at times been severe in adult patients. Other significant side effects include elevated bilirubin and inflammation at intravenous sites.

Quinupristin-dalfopristin is a significant inhibitor of CYP-450 3A4 and, therefore, must be used with caution in patients receiving drugs metabolized by this mechanism (eg, clarithromycin, itraconazole, erythromycin, and many others).
CEPHALOSPORINS

Cephalosporin agents make up a large and often confusing group of antimicrobials. Many of these drugs are similar in antibacterial spectrum and side effects and may have similar names. Clinicians should learn well the properties of one or two drugs in each class. Cephalosporins are often grouped as “generations” to signify their similar antimicrobial activity. First-generation cephalosporins such as cefazolin intravenously and cephalaxin orally are useful mainly for susceptible S. aureus infection and UTI due to susceptible E. coli. Second-generation cephalosporins, such as cefuroxime intravenously and cefprozil and cefuroxime orally, have somewhat reduced, but acceptable, activity against gram-positive cocci, and greater activity against some gram-negative rods compared with first-generation cephalosporins. They are active against H. influenzae and Moraxella catarrhalis, including strains that produce β-lactamase capable of inactivating ampicillin. Third-generation cephalosporins have substantially less activity against gram-positive cocci, such as S. aureus, but greatly augmented activity against aerobic gram-negative rods. Cefotaxime and ceftriaxone are examples of intravenous drugs, whereas cefpodoxime and cefibuten are representative oral drugs. Cefepime is often described as fourth-generation cephalosporins because of its broad activity against gram-positive and gram-negative organisms, including P. aeruginosa. Cefepime is stable to β-lactamase degradation and is a poor inducer of β-lactamase. Cefepime will be most useful for organisms resistant to other drugs.

Ceftaroline is a new cephalosporin that has expanded activity against MRSA and some Enterococcus faecalis, while retaining the gram-negative activity of third-generation cephalosporins. Ceftaroline does not have sufficient activity against P. aeruginosa or Acinetobacter to be useful. Ceftaroline is not approved for use in children younger than 18 years old.

No cephalosporin agent, except ceftaroline, has substantial activity against L. monocytogenes, enterococci, or MRSA. The only cephalosporins useful for treating anaerobic infections are cefoxitin and cefotetan, which are second-generation cephalosporins with excellent activity against B. fragilis. Ceftazidime and cefepime are cephalosporins with activity against P. aeruginosa.

Allergy to β-lactam antimicrobials is reported commonly by parents. Immediate hypersensitivity reactions, including anaphylaxis or hives, most commonly predict IgE-mediated allergy. In contrast, most delayed reactions and nonspecific rashes are likely due to the underlying infection or nonallergic reactions. (See Chapter 38.) Cephalosporins should be used with caution in children with immediate hypersensitivity reactions to penicillins or cephalosporins.

Resistance to cephalosporins is common among aerobic gram-negative rods. The presence of inducible cephalosporinases in some gram-negative rod organisms, such as P. aeruginosa, Serratia marcescens, Citrobacter, and Enterobacter, has led to clinical failures because of the emergence of resistance during therapy. Extended-spectrum β-lactamases mediate broad resistance to all penicillins, aminopenicillins, cephalosporins, and monobactams. Carbapenems, fluoroquinolones, or combinations including these drugs are used for serious infections due to gram-negative organisms with these enzymes. Active laboratory-based surveillance is necessary to detect resistance in these gram-negative organisms.

AZTREONAM

Aztreonam is the only monobactam antimicrobial agent approved in the United States. Although it is not approved for use in children younger than age 9 months, there is considerable pediatric experience with its use, including in neonates and premature infants. Aztreonam is active against aerobic gram-negative rods, including P. aeruginosa. Aztreonam has activity against H. influenzae and M. catarrhalis, including those that are β-lactamase producers. Most patients with allergy to penicillin or cephalosporins are not sensitized to aztreonam, except that children with prior reactions to ceftazidime may have reactions to aztreonam because aztreonam and ceftazidime have a common side chain.

Aztreonam delivered by aerosolization by a proprietary nebulization system is approved for therapy of Pseudomonas aeruginosa infection in patients with cystic fibrosis. Safety and efficacy have not been established in children younger than 7 years. Therapy is delivered three times daily for 28 days with a goal to improve respiratory symptoms.

CARBAPENEMS

Meropenem, ertapenem, doripenem, and imipenem are broad-spectrum β-lactam antimicrobials. Imipenem–cilastatin is a combination of an active antibiotic and cilastatin, which inhibits the metabolism of imipenem in the kidneys and thereby results in high serum and urine levels of imipenem. These carbapenems are also active against S. pneumoniae, including many penicillin- and cephalosporin-resistant strains. Carbapenems have been used successfully to treat meningitis and may be considered if vancomycin is not tolerated. An increased frequency of seizures is encountered when central nervous system infections are treated with carbapenems. These agents are broadly active against streptococci, methicillin-susceptible S. aureus, some enterococci, and gram-negative rods such as P. aeruginosa, β-lactamase–producing H. influenzae, and gram-negative anaerobes. Ertapenem has less activity against P. aeruginosa, Acinetobacter species, and Enterococcus species than meropenem and imipenem. Because carbapenems are active against so many species of bacteria, there is a strong temptation to use them as single-drug empiric therapy. Units that have used carbapenems heavily have encountered resistance in many different species of gram-negative rods.
MACROLIDES & AZALIDES

Erythromycin was once the most commonly used macrolide antimicrobial agent, but now azithromycin and clarithromycin are preferred because of decreased side effects. It is active against many bacteria that are resistant to cell wall–active antimicrobials, and is the drug of choice for Bordetella pertussis, Legionella pneumophila, C pneumoniae, M pneumoniae, and Chlamydia trachomatis infections (in children in whom tetracycline is not an option). Erythromycin is used for outpatient therapy of streptococcal and staphylococcal infections in patients with penicillin allergy. More serious infections due to streptococci and staphylococci are usually treated with penicillins, clindamycin, PRPs, or cephalosporins because of a significant incidence of erythromycin resistance in both species. S pneumoniae resistant to erythromycin and the related macrolides are now frequent in many communities. This limits the utility of macrolide antimicrobials for therapy of pneumonia, otitis media, and sinusitis. Gastrointestinal side effects are common. Interactions with theophylline, carbamazepine, terfenadine, cycloserine, and other drugs may require dosage modifications of erythromycin and clarithromycin. Significant interactions with azithromycin are less common. Erythromycin exposure is associated with pyloric stenosis in newborns, so azithromycin is preferred in most neonates.

Erythromycin is available in many formulations, including the base, estolate, ethyl succinate, and stearate, but is sometimes unavailable due to drug shortages and decreased prescribing of these drugs. Transient hepatic toxicity occurs in adults, but is much less common in children. Erythromycin base and stearate should be taken with meals for best absorption.

Clarithromycin and azithromycin, macrolide and azalide antimicrobials, respectively, are much less likely than erythromycin to cause nausea, vomiting, and diarrhea. These agents are useful in children who cannot tolerate erythromycin. Clarithromycin is more active than erythromycin against H influenzae, M catarrhalis, and Neisseria gonorrhoeae and is the drug of choice, usually in combination, for some nontuberculous mycobacterial infections. Azithromycin has a prolonged tissue half-life that achieves a prolonged antimicrobial effect. Azithromycin is dosed once daily for 5 days, but must be taken 1 hour before or 2 hours after meals because food interferes with absorption. Although azithromycin is active against H influenzae, some authors report poor eradication of H influenzae from the middle ear. Azithromycin can be used for single-dose therapy of C trachomatis infections. It is beneficial in adolescents when compliance with erythromycin or tetracycline is a concern. Azithromycin is useful for therapy of Shigella and Salmonella infections, including typhoid fever resistant to ampicillin and TMP-SMX. Alternatives include third-generation cephalosporins and fluoroquinolones. Clarithromycin is effective against Lyme disease, but amoxicillin is the drug of choice in young children. Clarithromycin and azithromycin are alternative drugs for toxoplasmosis in sulfonamide-allergic patients and as alternatives to erythromycin in legionellosis. In vitro and limited clinical experience in providing treatment to contacts of pertussis patients suggests efficacy equal to that of erythromycin. Clarithromycin and azithromycin are considerably more expensive than most erythromycin formulations, and for that reason are usually preferred, but they are advantageous by virtue of their twice-daily and once-daily dosing, respectively. Some failures of the newer macrolides have occurred in S pneumoniae sepsis and meningitis, perhaps because of low serum levels despite the high tissue levels achieved. High rates of resistance to macrolides and azalides have been encountered in some communities. The frequent use of azithromycin for respiratory infections and acute otitis media has contributed to selection of resistant strains. Azithromycin is not recommended as first-line therapy for S pneumoniae infection.

CLINDAMYCIN

Clindamycin is active against S aureus, some MRSA, S pyogenes, other streptococcal species except enterococci, and both gram-positive and gram-negative anaerobes. Clindamycin or metronidazole is frequently combined with other antimicrobials for empiric therapy of suspected anaerobic or mixed anaerobic and aerobic infections. Empiric use of clindamycin is justified in suspected anaerobic infections because cultures frequently cannot be obtained and, if obtained, may be slow in confirming anaerobic infection. Examples are pelvic inflammatory disease, necrotizing enterocolitis, other infections in which the integrity of the gastrointestinal or genitourinary tracts is compromised, and sinusitis. Clindamycin does not achieve high levels in CSF, but brain abscesses, toxoplasmosis, and other central nervous system infections, where disruption of the blood-brain barrier occurs, can be successfully treated with clindamycin. Clindamycin should be added to regimens for treatment of serious streptococcal and staphylococcal infections, such as necrotizing fasciitis and toxic shock syndrome. Both in vitro and clinical data suggest increased bactericidal killing, and improved outcomes occur with clindamycin. For most oral anaerobes (eg, in a dental abscess), penicillin is more active than clindamycin. Clindamycin has been associated with the occurrence of C difficile–related pseudomembranous colitis. Although diarrhea is a frequent side effect, pseudomembranous colitis is uncommonly due to clindamycin in children.

SULFONAMIDES

Sulfonamides—the oldest class of antimicrobials—remain useful for treatment of UTIs, and for other infections due to E coli and for Nocardia. Although useful for rheumatic fever prophylaxis in penicillin-allergic patients, sulfonamides fail
to eradicate group A streptococci and cannot be used for treatment of acute infections.

TMP-SMX is a fixed combination that is more active than either drug alone. Gram-positive cocci, including some S pneumoniae, many staphylococci, Haemophilus, and many gram-negative rods, are susceptible. Unfortunately, resistance to TMP-SMX has become more common. S pneumoniae resistant to penicillin and cephalosporins is often also resistant to TMP-SMX and erythromycin. In communities, where Shigella and Salmonella enteritidis strains remain susceptible, as do most E coli strains, TMP-SMX is very useful for treatment of both UTIs and bacterial dysentery. TMP-SMX is also the drug of choice for treatment or prophylaxis against Pneumocystis jiroveci infection. Myelosuppressive side effects especially anemia limit the use of TMP-SMX in some children infected with HIV.

Sulfonamide is associated with several cutaneous reactions, including urticaria, photosensitivity, Stevens-Johnson syndrome, purpura, and maculopapular rash. Hematologic side effects such as leukopenia, thrombocytopenia, and hemolytic anemia are uncommon. Common gastrointestinal side effects are nausea and vomiting. The dermatologic and hematologic side effects are thought to be more common and more severe with TMP-SMX than with sulfonamide alone.

**TETRACYCLINES**

Tetracyclines, which are effective against a broad range of bacteria, are not commonly used in children because alternative effective drugs are available. Many different tetracycline formulations are available. Tetracyclines are effective against B pertussis and E coli and many species of Rickettsia, Chlamydia, and Mycoplasma. Doxycycline or minocycline is the drug of choice for eradication of C trachomatis in pelvic inflammatory disease and nongonococcal urethritis.

Staining of permanent teeth was noted in young children given repeated courses of tetracyclines. As a result, tetracyclines are generally not given to children younger than age 9 years unless alternative drugs are unavailable. A single course of tetracycline does not pose a significant risk of tooth staining. Mucous membrane candidiasis, photosensitivity, nausea, and vomiting are other common side effects. Tetracycline should be taken on an empty stomach, either 1 hour before or 2 hours after a meal. Doxycycline is well absorbed even in the presence of food; administration with food may minimize gastrointestinal side effects. Doxycycline is often preferred because it is better tolerated than tetracycline, and twice-daily administration is convenient.

Tetracycline is used for therapy of rickettsial infections such as Rocky Mountain spotted fever, ehrlichiosis, rickettsialpox, murine typhus, and Q fever; as an alternative to erythromycin for M pneumoniae and C pneumoniae infections; and for treatment of psittacosis, brucellosis, P multocida infection, and relapsing fever.

Tigecycline is a new polyketide antimicrobial that is an analogue of tetracycline and a bacteriostatic inhibitor of protein synthesis. Tigecycline is active against gram-negative aerobes, anaerobes, and many gram-positive cocci including MRSA. It is approved for intravenous therapy of adults with complicated SSTIs and complicated intra-abdominal infections.

**AMINOGLYCOSIDES**

The aminoglycosides bind to ribosomal subunits and inhibit protein synthesis. They are active against aerobic gram-negative rods, including P aeruginosa. Streptomycin was the first drug in this class, but today it is used only to treat tuberculosis and the occasional cases of plague and tularemia.

Aminoglycosides are used to treat serious gram-negative infections and are given intravenously or intramuscularly. They are also used to treat pyelonephritis, suspected gram-negative sepsis, and in other settings where P aeruginosa infections are common, such as cystic fibrosis and burns. Aminoglycosides have activity against gram-positive organisms and, combined with penicillin or ampicillin, may achieve synergistic killing of L monocytogenes and group B streptococci. Penicillin, ampicillin, or vancomycin combined with gentamicin is indicated for therapy of serious enterococcal infections, such as sepsis or endocarditis because of more rapid clinical improvement with combined therapy. Aminoglycosides have activity against S aureus, but are always used in combination with other antistaphylococcal antibiotics.

Aminoglycosides are not active in an acidic environment and may not be effective against abscesses. Aminoglycosides diffuse poorly into the CSF and achieve only about 10% of serum concentrations. As a result, a third-generation cephalosporin is preferred for treatment of meningitis.

Aminoglycosides kill bacteria in a concentration-dependent manner. They also have a prolonged suppressive effect on the regrowth of susceptible organisms (postantibiotic effect). These principles have led some investigators to establish guidelines for once-daily dosing of aminoglycosides, using larger initial doses given every 24 hours. Although aminoglycosides are associated with both renal and eighth nerve toxicity, the entry of the drug into renal and cochlear cells is saturable. It therefore was predicted that once-daily dosing would result in less toxicity than traditional twice-daily or three-times-daily dosing. Studies in adult patients confirm that once-daily dosing is as efficacious as traditional dosing and is associated with less toxicity. Although there is extensive experience with dosing intervals of 18–36 hours in premature infants, small total daily doses are customarily used (2.0–2.5 mg/kg per dose of gentamicin or tobramycin). A convenient and cost-effective approach in children is based on the experience with adult patients and uses larger daily doses (4–7 mg/kg per dose every 24 hours).
Nevertheless, traditional twice-daily or three-times-daily dosing regimens of aminoglycosides, with monitoring of serum levels, are still widely used. Careful monitoring is necessary, particularly in children with abnormal or changing renal function, premature infants, and infants with rapidly changing volumes of distribution. Aminoglycosides are usually infused over 30–45 minutes, and the peak serum concentration is measured 30–45 minutes after the end of the infusion. A trough serum concentration is measured prior to the next dose. The efficacious and nontoxic serum concentrations for gentamicin and tobramycin are trough less than 2 mcg/mL and peak 5–10 mcg/mL; for amikacin, trough less than 10 mcg/mL and peak 15–25 mcg/mL (see Table 39–4). Aminoglycoside levels and creatinine levels should be measured in children expected to receive more than 3 days of therapy, and repeated weekly in children on long-term therapy, even when renal function is normal and stable.

**FLUOROQUINOLONES**

Modification of the quinolone structure of nalidixic acid has led to many new compounds called fluoroquinolones, which are well absorbed after oral administration and possess excellent antibacterial activity against resistant gram-negative pathogens. The currently available fluoroquinolones vary in their activity against specific organisms. Fluoroquinolones are active against most of the Enterobacteriaceae, including *E coli*, *Enterobacter*, *Klebsiella*, in some cases *P aeruginosa*, and many other gram-negative bacteria such as *H influenzae*, *M catarrhalis*, *N gonorrhoeae*, and *N meningitidis*. Some fluoroquinolones (ofloxacin and levofloxacin) are active against *C trachomatis* and *Mycoplasma*. The fluoroquinolones are active against some enterococci, *S aureus*, MRSA, and coagulase-negative staphylococci. The newer quinolones have good activity against penicillin- and cephalosporin-resistant *S pneumonia*.

Ciprofloxacin and its otic and ophthalmic preparations are the only fluoroquinolone antimicrobials currently approved for use in children older than 1 year, although fluoroquinolones offer very attractive alternatives to other approved agents. The objection to quinolones is based on the recognition that nalidixic acid and other quinolones cause arthropathy when tested experimentally in newborn animals of many species. The fear that children would also be more susceptible than adults to cartilage injury has not been realized in clinical experience. Both retrospective long-term follow-up studies of children given nalidixic acid and prospective studies of children receiving treatment under protocols with fluoroquinolones have shown similar rates of toxicity compared with adult patients. Arthropathy occurs uncommonly, although tendon rupture is a reported rare, serious complication which occurs more commonly in adults. For these reasons, quinolones should be considered for use in children when the benefit clearly outweighs the risk, when no alternative drug is available, and after discussion with the parents.

Ciprofloxacin is useful for oral therapy of resistant gram-negative UTIs, such as those caused by *P aeruginosa*. Fluoroquinolones are no longer recommended for single-dose therapy of gonorrhea due to frequent resistance, but ofloxacin and levofloxacin are an alternative therapy for treating *Chlamydia* infections and pelvic inflammatory disease. Ciprofloxacin, levofloxacin, and ofloxacin are used as therapy of resistant cases of shigellosis. Levofloxacin and ciprofloxacin are usually the drugs of choice for treatment of traveler’s diarrhea. Ciprofloxacin is useful for treatment of *P aeruginosa* infection in patients with cystic fibrosis, and as therapy for chronic suppurative otitis media. Several quinolones are used as therapy for pneumonia due to *Legionella*, *Mycoplasma*, or *C pneumoniae*, although a macrolide is often preferred, and as prophylactic therapy of meningococcal infection. Ofloxacin and levofloxacin are used for treatment of some cases of *Mycobacterium tuberculosis* and some atypical mycobacterial infections.

**METRONIDAZOLE**

Metronidazole has excellent activity against most anaerobes, particularly gram-negative anaerobes, such as *Bacteroides* and *Fusobacterium*, and against gram-positive anaerobes such as *Clostridium*, *Prevotella*, and *Porphyromonas*. Gram-positive anaerobic cocci such as *Peptococcus* and *Peptostreptococcus* are often more susceptible to penicillin or to clindamycin. Because metronidazole lacks activity against aerobic organisms, it is usually given with one or more other antibiotics. Metronidazole is well absorbed after oral administration and has excellent penetration into the central nervous system. Metronidazole is the drug of choice for bacterial vaginosis and for *C difficile* enterocolitis. It is active against many parasites, including *Giardia lamblia* and *Entamoeba histolytica*.

**DAPTOMYCIN**

Daptomycin has broad bactericidal activity against gram-positive cocci. Daptomycin is a lipopeptide that binds to bacterial cell membranes, resulting in membrane depolarization and cell death. Daptomycin is active against methicillin-sensitive and -resistant *S aureus*, *S pyogenes*, and *Streptococcus agalactiae*, as well as *E faecium* (including vancomycin-resistant strains) and *E faecalis* (vancomycin-sensitive strains). Daptomycin is given as a once-daily intravenous infusion of 4 mg/kg and is approved for therapy of complicated SSTIs in adults, but has not been sufficiently studied in children younger than 18 years to make recommendations for dosing and use. Daptomycin therapy of pneumonia was unsuccessful in a large percentage of cases, and should not be used. Daptomycin is excreted renally, so a modification of dosing is needed in patients with impaired renal function.
Nausea, constipation, and headache are the most common side effects of therapy. In patients with muscle pain, monitoring creatinine phosphokinase levels should be done.

**VIRAL INFECTIONS**

Viruses cause most pediatric infections. Mixed viral or viral-bacterial infections of the respiratory and intestinal tracts are very common, as is prolonged asymptomatic shedding of some viruses in childhood, especially in young children. Thus, the detection of a virus is not always proof that it is the cause of a given illness. Viruses are often a predisposing factor for bacterial respiratory infections (eg, otitis, sinusitis, and pneumonia).

Many respiratory and herpesviruses can now be detected within 24–48 hours by combining culture and monoclonal antibody techniques (“rapid culture technique”) or through antigen or nucleic acid detection techniques. These techniques are more rapid than isolation of viruses in tissue culture and in most cases are equally sensitive or more so. Polymerase chain reaction (PCR) amplification of viral genes has led to recognition of previously undetected infections. New diagnostic tests have changed some basic concepts about viral diseases and made diagnosis of viral infections both more certain and more complex. Only laboratories with excellent quality-control procedures should be used, and the results of new tests must be interpreted cautiously. The availability of specific antiviral agents increases the value of early diagnosis for some serious viral infections. New diagnostic tests have changed some basic concepts about viral diseases and made diagnosis of viral infections both more certain and more complex. Only laboratories with excellent quality-control procedures should be used, and the results of new tests must be interpreted cautiously. The availability of specific antiviral agents increases the value of early diagnosis for some serious viral infections.

**RESPIRATORY INFECTIONS**

Many viral infections can cause either upper or lower respiratory tract signs and symptoms, sometimes both in the same patient. Those that produce a predominance of these signs and symptoms are described in the text that follows. Many so-called respiratory viruses can also produce distinct nonrespiratory disease (eg, enteritis or cystitis or myocarditis caused by adenoviruses; parotitis caused by parainfluenza viruses). Respiratory viruses can cause disease in any area of the respiratory tree. Thus, they can cause coryza, pharyngitis, sinusitis, tracheitis, bronchitis, bronchiolitis, and pneumonia—although certain viruses tend to be closely associated with one anatomic area (eg, parainfluenza with croup, respiratory syncytial virus [RSV] with bronchiolitis) or discrete epidemics (eg, influenza, RSV, parainfluenza). Thus it is impossible on clinical grounds to be certain of the specific viral cause of an infection in a given child. This information, which is provided by the virology laboratory, is often important for epidemiologic, therapeutic, and preventive reasons. In immunocompromised patients these annoying, but otherwise benign, viruses can cause severe pneumonia.

**VIRUSES CAUSING THE COMMON COLD**

The common cold syndrome (also called upper respiratory infection) is characterized by combinations of runny nose, nasal congestion, sore throat, tearing, cough, and sneezing. Low-grade fever may be present. The causal agent is usually not sought or determined. Epidemiologic studies indicate that rhinoviruses, which are the most common cause (30%–40%; much more in some series), are present throughout the year, but are more prevalent in the colder months in temperate climates. Adenoviruses also cause colds in all seasons and epidemics are common. Respiratory syncytial virus, parainfluenza viruses, human metapneumovirus, and influenza viruses cause the cold syndrome during epidemics from late fall through winter. Multiple strains of coronaviruses account for 5%–10% of colds in winter. Equally prevalent in aggregate are other newly identified respiratory viruses such as the human bocavirus (a parvovirus) and several...

Polymaviruses. The precise role of these newly discovered viruses in childhood disease is under study. Enteroviruses cause the “summer cold.” One outcome of the common cold is morbidity continuing for 5–7 days. It is also likely that changes in respiratory epithelium, local mucosal swelling, and altered local immunity are sometimes the precursors of more severe illnesses such as otitis media, pneumonia, and sinusitis. During and following a cold, the bacterial flora changes and bacteria are found in normally sterile areas of the upper airway. Asthma attacks are frequently provoked by any of the viruses that cause the common cold. These “cold viruses” are a common cause of lower respiratory tract infection in young children. There is no evidence that antibiotics will prevent complications of the common cold, and the unjustified widespread use of antibiotics for cold symptoms has contributed to the emergence of antibiotic-resistant respiratory flora.

In 5%–10% of children, symptoms from these virus infections persist for more than 10 days. This overlap with the symptoms of bacterial sinusitis presents a difficult problem for clinicians, especially because colds can produce an abnormal computed tomography (CT) scan of the sinuses. Viruses that cause a minor illness in immunocompetent children, such as rhinoviruses, influenza, RSV, and metapneumovirus, can cause severe lower respiratory disease in immunologically or anatomically compromised children.

CRP, C-reactive protein; CSF, cerebrospinal fluid; EIA, enzyme immunoassay; ESR, erythrocyte sedimentation rate; GI, gastrointestinal; HHV-6, human herpesvirus 6; IFA, immunofluorescent assay; PCR, polymerase chain reaction; URI, upper respiratory infection.
There is conflicting evidence that symptomatic relief for children can be achieved with oral antihistamines, decongestants, or cough suppressants. The FDA has recommended that such over-the-counter medications not be used in children less than 2 years old. Topical decongestants provide temporary improvement in nasal symptoms. Vitamin C has not been shown to have a significant preventative or therapeutic role. Zinc therapy of the common cold and prevention with zinc may be effective in adults, but there is great uncertainty about dosing and some adverse effects. Humidified air and garlic do not alter the course of colds.

INFECTIONS DUE TO ADENOVIRUSES

■ Multiple syndromes, depending on the type of adenovirus.
■ Upper respiratory infections; most notable is severe pharyngitis with tonsillitis and cervical adenopathy.
■ Conjunctivitis.
■ Pneumonia.
■ Enteric adenoviruses cause mild diarrheal illnesses.
■ Definitive diagnosis by antigen detection, PCR, or culture.

There are 57 types of adenoviruses, which account for 5%–15% of all respiratory illnesses in childhood, usually pharyngitis or tracheitis, but including 5% of childhood lower respiratory tract infections. Adenoviral infections, which are common early in life (most prior to age 2 years), occur 3–10 days after exposure to respiratory droplets or fomites. Enteric adenoviruses are an important cause of childhood diarrhea. Epidemic respiratory disease from adenoviruses occurs in winter and spring, especially in closed environments such as day care centers and institutions.

Because of latent infection in lymphoid tissue, asymptomatic shedding from the respiratory or intestinal tract is common.

Specific Adenoviral Syndromes

A. Pharyngitis

Pharyngitis is the most common adenoviral disease, and the most common viral cause of severe pharyngitis in children. Fever and adenopathy are common. Tonsillitis may be exudative. Rhinitis and an influenza-like systemic illness may be present. Laryngotracheitis or bronchitis may accompany pharyngitis.

B. Pharyngoconjunctival Fever

Conjunctivitis may occur alone and be prolonged, but most often is associated with preauricular adenopathy, fever, pharyngitis, and cervical adenopathy. Foreign body sensation in the eye and other symptoms last less than a week. Lower respiratory symptoms are uncommon.

C. Epidemic Keratoconjunctivitis

Symptoms are severe conjunctivitis with punctate keratitis and occasionally visual impairment. A foreign body sensation, photophobia, and swelling of conjunctiva and eyelids are characteristic. Preauricular adenopathy and subconjunctival hemorrhage are common.

D. Pneumonia

Severe pneumonia may occur at all ages. It is especially common in young children (age < 3 years). Chest radiographs show bilateral peribronchial and patchy ground-glass interstitial infiltrates in the lower lobes. Symptoms persist for 2–4 weeks. Adenoviral pneumonia can be necrotizing and cause permanent lung damage, especially bronchiectasis. A pertussis-like syndrome with typical cough and lymphocytosis can occur with lower respiratory tract infection. A new variant of adenovirus serotype 14 can cause unusually severe, sometimes fatal pneumonia in children and adults.

E. Rash

A diffuse morbilliform (rarely petechial) rash resembling measles, rubella, or roseola may be present. Koplik spots are absent.

F. Diarrhea

Enteric adenoviruses (types 40 and 41) cause 3%–5% of cases of short-lived diarrhea in afebrile children, especially in those less than 4 years old.

G. Mesenteric Lymphadenitis

Fever and abdominal pain may mimic appendicitis. Pharyngitis is often associated. Adenovirus-induced adenopathy may be a factor in appendicitis and intussusception.
H. Other Syndromes

Immunosuppressed patients, including neonates, may develop severe or fatal pulmonary or gastrointestinal infections or multisystem disease. Hemorrhagic cystitis can be a serious problem in immunocompromised children. Other rare complications that can occur in the immune competent child include encephalitis, hepatitis, and myocarditis. Adenoviruses have been implicated in the syndrome of idiopathic myocardiopathy.

Laboratory & Diagnostic Studies

Diagnosis can be made by conventional culture of conjunctival, respiratory, or stool specimens, but several days to weeks are required. Viral culture using the rapid culture technique with immunodiagnostic reagents detects adenovirus in 48 hours. Adenovirus infection can also be diagnosed using these reagents directly on respiratory secretions. This is quicker, but less sensitive, than the culture methods. PCR is an important, relatively rapid and sensitive diagnostic method for adenovirus infections. Special cells are needed to isolate enteric adenoviruses. ELISA tests rapidly detect enteric adenoviruses in diarrheal specimens. Respiratory adenovirus infections can be detected retrospectively by comparing acute and convalescent sera, but this is not helpful during an acute illness.

Treatment

There is no specific treatment for adenovirus infections. Intravenous immuno globulin (IVIG) may be tried in immunocompromised patients with severe pneumonia. There are anecdotal reports of successful treatment of immunocompromised patients with cidofovir, which inhibits adenovirus in vitro.

INFLUENZA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fever, cough, pharyngitis, malaise, congestion.
- Pneumonia.
- Encephalitis.

Seasonal: late fall through mid-spring.

Detection of virus, viral antigens, or nucleic acid in respiratory secretions.

Symptomatic infections are common in children because they lack immunologic experience with influenza viruses. Infection rates in children are greater than in adults and are instrumental in initiating community outbreaks. Epidemics occur in fall and winter. Three main types of influenza viruses (A/H1N1, A/H3N2, B) cause most human epidemics, with antigenic drift ensuring a supply of susceptible hosts of all ages. In recent years, avian influenza A/H5N1 has caused isolated human outbreaks in Asia that are associated with high rates of hospitalization and death. A swine-origin influenza A/H1N1 initiated a human pandemic in the spring of 2009. Almost 50 million Americans were infected with this virus in 2009. Illnesses caused by this virus tend to be more severe in older children and young adults. In addition, the rates of hospitalization and death are higher than typically observed with seasonal influenza.

Clinical Findings

Spread of influenza occurs by way of airborne respiratory secretions. The incubation period is 2–7 days.

A. Symptoms and Signs

Influenza infection in older children and adults produces a characteristic syndrome of sudden onset of high fever, severe myalgia, headache, and chills. These symptoms overshadow the associated coryza, pharyngitis, and cough. Usually absent are rash, marked conjunctivitis, adenopathy, exudative pharyngitis, and dehydrating enteritis. Fever, diarrhea, vomiting, and abdominal pain are common in young children. Infants may develop a sepsis-like illness and apnea. Chest examination is usually unremarkable. Unusual clinical findings include croup (most severe with type A influenza), exacerbation of asthma, myositis (especially calf muscles), myocarditis, parotitis, encephalopathy (distinct from Reye syndrome), nephritis, and a transient maculopapular rash. Acute illness lasts 2–5 days. Cough and fatigue may last several weeks. Viral shedding may persist for several weeks in young children.

B. Laboratory Findings

The leukocyte count is normal to low, with variable shift. Influenza infections may be more difficult to recognize in children than in adults even during epidemics, and therefore a specific laboratory test is highly recommended. The virus can be found in respiratory secretions by direct fluorescent antibody staining of nasopharyngeal epithelial cells, ELISA,
optic immunoassay (OIA), and PCR. PCR has the highest sensitivity and specificity, close to 100%, and is rapidly becoming the preferred test. It can also be cultured within 3–7 days from pharyngeal swabs or throat washings. Many laboratories use the rapid culture technique by centrifuging specimens onto cultured cell layers and detecting viral antigen after 48 hours. Other body fluids or tissues (except lung) rarely yield the virus in culture and are more appropriately tested by PCR, which, due to its high sensitivity, can increase influenza detection in respiratory specimens. A late diagnosis may be made with paired serology, using hemagglutination inhibition assays.

C. Imaging

The chest radiograph is nonspecific; it may show hyperaeration, peribronchial thickening, diffuse interstitial infiltrates, or bronchopneumonia in severe cases. Hilar nodes are not enlarged. Pleural effusion is rare in uncomplicated influenza.

Differential Diagnosis

The following may be considered: all other respiratory viruses, *Mycoplasma pneumoniae* or *Chlamydia pneumoniae* (longer incubation period, prolonged illness), streptococcal pharyngitis (pharyngeal exudate or petechiae, adenitis, no cough), bacterial sepsis (petechial or purpuric rash may occur), toxic shock syndrome (rash, hypotension), and ricketsial infections (rash, different season, insect exposure). High fever, the nature of preceding or concurrent illness in family members, and the presence of influenza in the community are distinguishing features from parainfluenza or RSV infections.

Complications & Sequelae

Lower respiratory tract symptoms are most common in children younger than age 5 years. Hospitalization rates are highest in children younger than 2 years. Influenza can cause croup in these children. Secondary bacterial infections (classically staphylococcal) of the middle ear, sinuses, or lungs (pneumococcal was common in the swine-origin H1N1 pandemic of 2009) are common. Of the viral infections that precede Reye syndrome, varicella and influenza (usually type B) are most notable. During an influenza outbreak, ill children who develop protracted vomiting or irrational behavior should be evaluated for Reye syndrome. Influenza can also cause viral or postviral encephalitis, with cerebral symptoms much more prominent than those of the accompanying respiratory infection. Although the myositis is usually mild and resolves promptly, severe rhabdomyolysis and renal failure have been reported.

Children with underlying cardiopulmonary, metabolic, neuromuscular, or immunosuppressive disease may develop severe viral pneumonia. During the H1N1 pandemic, new high risk conditions were described: obesity and the first 2 weeks of postpartum.

Prevention

The trivalent inactivated influenza vaccine is moderately protective in older children (see Chapter 10). A live attenuated influenza vaccine (FluMist) is significantly more efficacious in children and is currently recommended for immunocompetent children 2 years of age or older. It is currently recommended that all children 6 months and older, and adults should be immunized with one of the available influenza vaccines, and that two doses be administered during the first year of immunization to children less than 9 years old. There is an ongoing effort to broaden the influenza B coverage by adding an additional influenza B strain to the seasonal vaccine. Quadrivalent live attenuated and inactivated influenza vaccines have been approved by the FDA; the quadrivalent live vaccine will become available for the 2013–2014 season. Widespread resistance to adamantanes of seasonal influenza A H3N2 and pandemic influenza A H1N1/2009 has made these drugs obsolete for the treatment and prevention of influenza. For prophylaxis oseltamivir is the most widely used agent (children < 15 kg, 30 mg daily; those 15–23 kg, 45 mg daily; those 23–40 kg, 60 mg daily; and those > 40 kg, 75 mg daily). Zanamivir (10 mg daily inhalations) can also be used in children older than age 5 years. Chemoprophylaxis should be considered during an epidemic for high-risk children who cannot be immunized or who have not yet developed immunity (about 6 weeks after primary vaccination or 2 weeks after a booster dose). For outbreak prophylaxis, therapy should be maintained for 2 weeks or more and for 1 week after the last case of influenza is diagnosed.

Treatment & Prognosis

Treatment consists of general support and management of pulmonary complications, especially bacterial superinfections. Antivirals are of benefit against seasonal influenza in immunocompetent hosts if begun within 48 hours after symptom onset. Treatment duration is 5 days and the doses are twice those used for prophylaxis (see earlier). Studies in immunocompromised patients during the 2009/2010 pandemic showed that oseltamivir was useful in this population even when initiated later than 2 days after the onset of disease.

Recovery is usually complete unless severe cardiopulmonary or neurologic damage has occurred. Fatal cases occur in very young infants, immunodeficient and anatomically compromised children, pregnant women including the first 2 weeks of postpartum, and obese individuals.

Effective treatment or prophylaxis of influenza in children markedly reduces the incidence of acute otitis media and antibiotic usage during the flu season.
PARAINFLUENZA (CROUP)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fever, nasal congestion, sore throat, cough.
- Croup.
- Detection of live virus, antigens, or nucleic acid in respiratory secretions.

Parainfluenza viruses (types 1–4) are the most important cause of croup. Most infants are infected with type 3 within the first 3 years of life, often in the first year. Type 3 appears annually, with a peak in the spring or summer. Infection with types 1 and 2 is experienced gradually over the first 5 years of life, usually during outbreaks in the fall; most primary infections are symptomatic and frequently involve the lower respiratory tract. The concept that parainfluenza 4 is less pathogenic is currently being reevaluated. Its epidemiology seems to overlap with that of parainfluenza 3.

Clinical Findings

A. Symptoms and Signs

Clinical diseases include febrile upper respiratory infection (especially in older children with reexposure), laryngitis, tracheobronchitis, croup, and bronchiolitis (second most common cause after RSV). The relative incidence of these manifestations is type-specific. Parainfluenza viruses (especially type 1) cause 65% of cases of croup in young children, 25% of tracheobronchitis, and 50% of laryngitis. Croup is characterized by a barking cough, inspiratory stridor (especially when agitated), and hoarseness. Type 2 parainfluenza is more likely to cause bronchiolitis. Parainfluenza virus can cause pneumonia in infants and immunodeficient children, and causes particularly high mortality among stem cell recipients. Onset is acute. Most children are febrile. Symptoms of upper respiratory tract infection often accompany croup.

B. Laboratory Findings

Diagnosis is often based on clinical findings. These viruses can be identified by conventional or rapid culture techniques (48 hours), by direct immunofluorescence on nasopharyngeal epithelial cells in respiratory secretions (<3 hours), or by PCR (<24 hours).

Differential Diagnosis

Parainfluenza-induced respiratory syndromes are difficult to distinguish from those caused by other respiratory viruses. Viral croup must be distinguished from epiglottitis caused by Haemophilus influenzae (abrupt onset, toxicity and high fever, drooling, dyspnea, little cough, left shift of blood smear, and a history of inadequate immunization).

Treatment

No specific therapy or vaccine is available. Croup management is discussed in Chapter 19. Ribavirin is active in vitro and has been used in immunocompromised children, but its efficacy is unproved.

RESPIRATORY SYNCYTIAL VIRUS DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Diffuse wheezing and tachypnea following upper respiratory symptoms in an infant (bronchiolitis).
- Epidemics in late fall to early spring (January–February peak).
- Hyperinflation on chest radiograph.
- Detection of RSV antigen or nucleic acid in nasal secretions.

General Considerations

RSV is the most important cause of lower respiratory tract illness in young children, accounting for more than 70% of cases of bronchiolitis and 40% of cases of pneumonia. RSV is a ubiquitous virus of early childhood. Almost all children develop upper respiratory symptoms; of these 20%–30% will develop lower respiratory infection. Outbreaks occur annually, and attack rates are high; 60% of children are infected in the first year of life, and 90% by age 2 years. During peak season (cold weather in temperate climates), the clinical diagnosis of RSV infection in infants with bronchiolitis is as accurate as most laboratory tests. Despite the presence of serum antibody, reinfecation is common. Two distinct genotypes can co-circulate or one may predominate in a community. Yearly shift in prevalence of these genotypes is a partial
explanation for reinfection. However, reinfection generally causes only upper respiratory symptoms in anatomically normal children. Immunosuppressed patients may develop progressive severe pneumonia. Children with congenital heart disease with increased pulmonary blood flow, children with chronic lung disease (eg, cystic fibrosis), and premature infants younger than age 6 months (especially when they have chronic lung disease of prematurity) are also at higher risk for severe illness. No vaccine is available.

Clinical Findings

A. Symptoms and Signs

Initial symptoms are those of upper respiratory infection. Low-grade fever may be present. The classic disease is bronchiolitis, characterized by diffuse wheezing, variable fever, cough, tachypnea, difficulty feeding, and, in severe cases, cyanosis. Hyperinflation, crackles, prolonged expiration, wheezing, and retractions are present. The liver and spleen may be palpable because of lung hyperinflation, but are not enlarged. The disease usually lasts 3–7 days in previously healthy children. Fever is present for 2–4 days; it does not correlate with pulmonary symptoms and may be absent during the height of lung involvement.

Apnea, poor feeding, and lethargy may be presenting manifestations, especially in premature infants, in the first few months of life. Apnea usually resolves after a few days, often being replaced by obvious signs of bronchiolitis.

RSV infection in older children is more likely to cause tracheobronchitis or upper respiratory tract infection. Exceptions are immunocompromised children and those with severe chronic lung or heart disease, who may have especially severe or prolonged primary infections and are subject to additional attacks of severe pneumonia.

B. Laboratory Findings

Rapid detection of RSV antigen in nasal or pulmonary secretions by fluorescent antibody staining or ELISA requires only several hours and is more than 90% sensitive and specific. Real-time PCR is more sensitive than antigen testing, but is more expensive. Often the PCR is multiplexed to detect four or more viral respiratory pathogens in the same assay. Rapid tissue culture methods take 48 hours and have comparable sensitivity, but require a carefully collected and handled specimen.

C. Imaging

Diffuse hyperinflation and peribronchiolar thickening are most common; atelectasis and patchy infiltrates also occur in uncomplicated infection, but pleural effusions are rare. Consolidation (usually subsegmental) occurs in 25% of children with lower respiratory tract disease.

Differential Diagnosis

Although almost all cases of bronchiolitis are due to RSV during an epidemic, other viruses, including parainfluenza, rhinovirus, and especially human metapneumovirus, cannot be excluded. Mixed infections with other viruses, chlamydiae, or bacteria can occur. Wheezing may be due to asthma, a foreign body, or other airway obstruction. RSV infection may closely resemble chlamydial pneumonitis when fine crackles are present and fever and wheezing are not prominent. The two may also coexist. Cystic fibrosis may present with respiratory symptoms resembling RSV infection; a positive family history or failure to thrive associated with GI symptoms, hyponatremia or hypoalbuminemia should prompt a sweat chloride test. Pertussis should also be considered in this age group, especially if cough is prominent and the infant is younger than age 6 months. A markedly elevated leukocyte count should suggest bacterial superinfection (neutrophilia) or pertussis (lymphocytosis).

Complications

RSV commonly infects the middle ear. Symptomatic otitis media is more likely when secondary bacterial infection is present (usually due to pneumococci or H influenzae). This is the most common complication (10%–20%) of RSV infection. Bacterial pneumonia complicates only 0.5%–1% of hospitalized patients. Sudden exacerbations of fever and leukocytosis should suggest bacterial infection. Respiratory failure or apnea may require mechanical ventilation, but occurs in less than 2% of hospitalized previously healthy full-term infants. Cardiac failure may occur as a complication of pulmonary disease or myocarditis. RSV commonly causes exacerbations of asthma. Nosocomial RSV infection is so common during outbreaks that elective hospitalization or surgery, especially for those with underlying illness, should be postponed. Well-designed hospital programs to prevent nosocomial spread are imperative (see next section).

Prevention & Treatment

Children who are very hypoxic or cannot feed because of respiratory distress must be hospitalized and given humidified oxygen as directed by oxygen saturation, and given tube or intravenous feedings. Antibiotics, decongestants, and expectorants are of no value in routine infections. RSV-infected children should be kept in respiratory isolation. Cohorting ill infants in respiratory isolation during peak season (with or without rapid diagnostic attempts) and emphasizing good hand washing may greatly decrease nosocomial transmission.

The utility of bronchodilator therapy alone has not been consistently demonstrated. Often a trial of bronchodilator therapy is given to determine response and is subsequently discontinued if there is no improvement. Racemic epinephrine occasionally works when β-agonists fail. This therapeutic
trial should only be undertaken in a hospital setting and care taken to observe children for an extended period after a positive response. The use of corticosteroids is also controversial in RSV bronchiolitis without complicating features such as asthma and chronic lung disease of prematurity. A meta-analysis of numerous studies of corticosteroid therapy indicated a significant effect on hospital stay, especially in those most ill at the time of treatment, but use of a single dose of corticosteroids in an outpatient setting had no lasting effect on respiratory status and did not prevent hospitalization. The combined use of racemic epinephrine and 5 days of oral dexamethasone significantly reduced hospitalization in one trial, but needs more evaluation before it can be recommended.

Ribavirin is the only licensed antiviral therapy used for RSV infection. It is given by continuous aerosolization. It is rarely used in infants without significant anatomic or immunologic defects. At best, there is a very modest effect on disease severity in immunocompetent infants with no underlying anatomic abnormality. Even in high-risk infants, a favorable clinical response to ribavirin therapy was not demonstrated in several studies, although some data suggest that it might be more efficacious if initiated early in the illness. Nevertheless, ribavirin is sometimes used in severely ill children who are immunologically or anatomically compromised and in those with severe cardiac disease.

Monthly intramuscular administration of humanized RSV monoclonal antibody is now recommended to prevent severe disease in selected high-risk patients during epidemic periods. Monthly administration should be considered during the RSV season for high-risk children (described in Chapter 10). Use of passive immunization for immunocompromised children is logical but not established. RSV antibody is not effective for treatment of established infection.

**Prognosis**

Although mild bronchiolitis does not produce long-term problems, 30%–40% of patients hospitalized with this infection will wheeze later in childhood, and RSV infection in infancy may be an important precursor to asthma. Chronic restrictive lung disease and bronchiolitis obliterans are rare sequelae.

**General Considerations**

Human metapneumovirus (hMPV) is a common agent of respiratory tract infections that is very similar to RSV in epidemiologic and clinical characteristics. Like RSV, parainfluenza, mumps, and measles, hMPV belongs to the paramyxovirus family. Humans are its only known reservoir. Seroepidemiologic surveys indicate that the virus has worldwide distribution. More than 90% of children contract hMPV infection by age 5 years, typically during late autumn through early spring outbreaks. hMPV accounts for 15%–25% of the cases of bronchiolitis and pneumonia in children younger than 2 years. Older children and adults can also develop symptomatic infection.

**Clinical Findings**

**A. Symptoms and Signs**

The most common symptoms are fever, cough, rhinorrhea, and sore throat. Bronchiolitis and pneumonia occur in 40%–70% of the children who acquire hMPV before the age of 2 years. Asymptomatic infection is uncommon. Other manifestations include otitis, conjunctivitis, diarrhea, and myalgia. Acute wheezing has been associated with hMPV in children of all ages, raising the possibility that this virus, like RSV, might trigger reactive airway disease. Dual infection with hMPV and RSV or other respiratory viruses seems to be a common occurrence and may increase morbidity and mortality.

**B. Laboratory Findings**

The virus has very selective tissue culture tropism, which accounts for its late discovery in spite of its presence in archived specimens from the mid-1950s. The preferred method of diagnosis is PCR performed on respiratory specimens. Rapid shell vial culture is an acceptable, albeit less sensitive, alternative. Antibody tests are available, but are most appropriately used for epidemiologic studies.

**C. Imaging**

Lower respiratory tract infection frequently shows hyperinflation and patchy pneumonitis on chest radiographs.
Treatment & Prognosis

No antiviral therapy is available to treat hMPV. Ribavirin has in vitro activity against human metapneumovirus, but there are no data to support its therapeutic value. Children with lower respiratory tract disease may require hospitalization and ventilatory support, but less frequently than with RSV-associated bronchiolitis. Duration of hospitalization in hMPV is typically shorter than in RSV.

INFECTIONS DUE TO ENTEROVIRUSES

Essentials of Diagnosis & Typical Features

- Acute febrile illness with headache and sore throat.
- Summer–fall epidemics.
- Other common features: rash, nonexudative pharyngitis.
- Common cause of aseptic meningitis.
- Complications: myocarditis, neurologic damage, life-threatening illness in newborns.

Enteroviruses are a major cause of illness in young children. The multiple types have similar nucleic acid and protein components, and may produce identical syndromes, but they differ antigenically, which makes vaccine development impractical and has hindered development of antigen detection and serologic tests. However, common RNA sequences and group antigens have led to diagnostic tests for viral nucleic acid and proteins. A PCR assay is available in many medical centers, but tissue culture is still used in some centers as a diagnostic method for echoviruses, polioviruses, and coxsackie B viruses. Although cultures may turn positive in 2–4 days, the relatively rapid answer obtained with PCR facilitates clinical decisions, particularly in cases of meningococcal meningitis and severe unexplained illness in neonates.

Parechoviruses are a genus of the family picornaviruses which were formerly considered to be enteroviruses (echoviruses 22 and 23). It is now realized that these are responsible for a significant number of pediatric infections. Some of the 15 types of parechoviruses infect almost every child before the age of 2 years; others before age 5 years.

Transmission of enteroviruses is fecal-oral or from upper respiratory secretions. Multiple enteroviruses circulate in the community at any one time; summer–fall outbreaks are common in temperate climates, but infections are seen year-round. After poliovirus, coxsackie B virus is most virulent, followed by echovirus. Neurologic, cardiac, and overwhelming neonatal infections are the most severe forms of illness.

ACUTE FEBRILE ILLNESS

Accompanied by nonspecific upper respiratory or enteric symptoms, the sudden onset of fever and irritability in infants or young children is often enteroviral in origin, especially in late summer and fall. More than 90% of enteroviral infections are not distinctive. Occasionally a petechial rash is seen; more often a diffuse maculopapular or morbilliform eruption (often prominent on palms and soles) occurs on the second to fourth day of fever. Rapid recovery is the rule. More than one febrile enteroviral illness can occur in the same patient in one season. The leukocyte count is usually normal. Infants, because of fever and irritability, may undergo an evaluation for bacteremia or meningitis and be hospitalized to rule out sepsis. Approximately half of these infants have aseptic meningitis. In the summer months enterovirus infection is more likely than human herpesvirus 6 (HHV-6) to cause an acute medical visit for fever. Duration of illness is 4–5 days.

RESPIRATORY TRACT ILLNESSES

1. Febrile Illness with Pharyngitis

This syndrome is most common in older children, who complain of headache, sore throat, myalgia, and abdominal discomfort. The usual duration is 3–4 days. Vesicles or papules may be seen in the pharynx. There is no exudate. Occasionally, enteroviruses are the cause of croup, bronchiitis, or pneumonia. They may also exacerbate asthma.

2. Herpangina

Herpangina is characterized by an acute onset of fever and posterior pharyngeal grayish white vesicles that quickly form ulcers (< 20 in number), often linearly arranged on the posterior palate, uvula, and tonsillar pillars. Bilateral faucial ulcers may also be seen. Dysphagia, vomiting, abdominal pain, and anorexia also occur and, rarely, parotitis or vaginal ulcers. Symptoms disappear in 4–5 days. The epidemic form is due to several coxsackie A viruses; coxsackie B viruses and echoviruses cause sporadic cases.

The differential diagnosis includes primary herpes simplex gingivostomatitis (ulcers are more prominent
anteriorly, and gingivitis is present), aphthous stomatitis (fever absent, recurrent episodes, anterior lesions), trauma, hand-foot-and-mouth disease (see later discussion), and Vincent angina (painful gingivitis spreading from the gum line, underlying dental disease). If the enanthema is missed, tonsillitis might be incorrectly diagnosed.

3. Acute Lymphonodular Pharyngitis

Coxsackievirus A10 has been associated with a febrile pharyngitis characterized by nonulcerative yellow-white posterior pharyngeal papules in the same distribution as herpangina. The duration is 1–2 weeks; therapy is supportive.

4. Pleurodynia (Bornholm Disease, Epidemic Myalgia)

Caused by coxsackie B virus (epidemic form) or many nonpolio enteroviruses (sporadic form), pleurodynia is associated with an abrupt onset of unilateral or bilateral spasmodic pain of variable intensity over the lower ribs or upper abdomen. Associated symptoms include headache, fever, vomiting, myalgias, and abdominal and neck pain. Physical findings include fever, chest muscle tenderness, decreased thoracic excursion, and occasionally a friction rub. The chest radiograph is normal. Hematologic tests are nondiagnostic. The illness generally lasts less than 1 week.

This is a disease of muscle, but the differential diagnosis includes bacterial pneumonia, bacterial and tuberculous effusion, and endemic fungal infections (all excluded radiographically and by auscultation),costochondritis (no fever or other symptoms), and a variety of abdominal problems, especially those causing diaphragmatic irritation.

There is no specific therapy. Potent analgesic agents and chest splinting alleviate the pain.

Cardiac Involvement

Myocarditis and pericarditis can be caused by a number of nonpolio enteroviruses, particularly type B coxsackieviruses. Most commonly, upper respiratory symptoms are followed by substernal pain, dyspnea, and exercise intolerance. A friction rub or gallop may be detected. Ultrasound will define ventricular dysfunction or pericardial effusion, and electrocardiography may show pericarditis or ventricular irritability. Creatine phosphokinase may be elevated. The disease may be mild or fatal; most children recover completely. In infants, other organs may be involved at the same time; in older patients, cardiac disease is usually the sole manifestation (see Chapter 20 for therapy). Enteroviral RNA is present in cardiac tissue in some cases of dilated cardiomyopathy or myocarditis; the significance of this finding is unknown. Epidemics of enterovirus 71, which occur in Asia, as well as sporadic cases in the United States, are associated with severe left ventricular dysfunction and pulmonary edema following typical mucocutaneous manifestations of enterovirus infection. Enterovirus 71 also can cause isolated severe neurologic disease or neurologic disease in combination with myocardial disease.

Severe Neonatal Infection

Sporadic and nosocomial nursery cases of severe systemic enteroviral disease occur. Clinical manifestations include combinations of fever, rash, pneumonitis, encephalitis, hepatitis, gastroenteritis, myocarditis, pancreatitis, and myositis. The infants, usually younger than 1 week, may appear septic, with cyanosis, dyspnea, and seizures. The differential diagnosis includes bacterial and herpes simplex infections, necrotizing enterocolitis, other causes of heart or liver failure, and metabolic diseases. Diagnosis is suggested by the finding of cerebrospinal fluid (CSF) mononuclear pleocytosis and confirmed by the isolation of virus or detection of enteroviral RNA in urine, stool, CSF, or pharynx. Therapy is supportive. IVIG is often administered, but its value is uncertain. Passively acquired maternal antibody may protect newborns from severe disease. For this reason, labor should not be induced in pregnant women near term who have suspected enteroviral disease. Some of these infections are now known to be caused by parechoviruses.

Rashes (Including Hand-Foot-And-Mouth Disease)

The rash can be macular, maculopapular, urticarial, scarlatiniform, petechial, or vesicular. One of the most characteristic is that of hand-foot-and-mouth disease (caused by coxsackieviruses, especially types A5, A10, and A16), in which vesicles or red papules are found on the tongue, oral mucosa, hands, and feet. Often they appear near the nails and on the heels. Associated fever, sore throat, and malaise are mild. The rash may appear when fever abates, simulating roseola.

CENTRAL NERVOUS SYSTEM ILLNESSES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Inadequate immunization or underlying immune deficiency.
- Headache, fever, muscle weakness.
- Aseptic meningitis.
- Asymmetrical, flaccid paralysis; muscle tenderness and hyperesthesia; intact sensation; late atrophy.

1. Poliomyelitis

General Considerations

Poliomavirus infection is subclinical in 90%–95% of cases; it causes nonspecific febrile illness in about 5% of cases and aseptic meningitis, with or without paralytic disease, in 1%–3%. In endemic areas, most of older children and adults are immune because of prior inapparent infections. Occasional cases in the United States occur in patients who travel to foreign countries or come in contact with visitors from areas that have poliovirus outbreaks. Severe poliovirus infection was a rare complication of OPV (oral poliovirus vaccine) vaccination as a result of reversion of the vaccine virus. The incidence of vaccine-associated paralytic poliomyelitis (VAPP) in the United States was 1:750,000 and 1:2.4 million doses for the first and second dose of OPV, respectively. Although rare, VAPP became more common than wild-type poliomyelitis in the United States in the 1980s. This led to a change in the recommended immunization regimen, substituting inactivated poliovirus vaccine (IPV) for OPV (see Chapter 10).

Clinical Findings

A. Symptoms and Signs

The initial symptoms are fever, myalgia, sore throat, and headache for 2–6 days. In less than 10% of infected children, several symptom-free days are followed by recurrent fever and signs of aseptic meningitis: headache, stiff neck, spinal rigidity, and nausea. Mild cases resolve completely. In only 1%–2% of these children do high fever, severe myalgia, and anxiety portend progression to loss of reflexes and subsequent flaccid paralysis. Sensation remains intact, although hyperesthesia of skin overlying paralyzed muscles is common and pathognomonic.

Paralysis is usually asymmetrical. Proximal limb muscles are more often involved than distal, and lower limb involvement is more common than upper. Bulbar involvement affects swallowing, speech, and cardiorespiratory function and accounts for most deaths. Bladder distention and marked constipation characteristically accompany lower limb paralysis. Paralysis is usually complete by the time the temperature normalizes. Weakness often resolves completely. Atrophy is usually apparent by 4–8 weeks. Most improvement of muscle paralysis occurs within 6 months.

B. Laboratory Findings

In patients with meningeal symptoms, the CSF contains up to several hundred leukocytes (mostly lymphocytes) per μL; the glucose level is normal, and protein concentration is mildly elevated. Poliovirus is easy to grow in cell culture and can be readily differentiated from other enteroviruses. It is rarely isolated from spinal fluid but is often present in the throat and stool for several weeks following infection. Paired serology is also diagnostic. Laboratory methods are available to differentiate wild from attenuated vaccine isolates.

Differential Diagnosis

Aseptic meningitis due to poliovirus is indistinguishable from that due to other viruses. Paralytic disease in the United States is usually due to nonpolio enteroviruses. Polio may resemble Guillain-Barré syndrome (minimal sensory loss, ascending symmetrical loss of function; minimal pleocytosis, high protein concentration in spinal fluid), polyneuritis (sensory loss), pseudoparalysis due to bone or joint problems (eg, trauma, infection), botulism, or tick paralysis.

Complications & Sequelae

Complications are the result of the acute and permanent effects of paralysis. Respiratory, pharyngeal, bladder, and bowel malfunction are most critical. Deaths are usually due to complications arising from respiratory dysfunction. Limbs injured near the time of infection, such as by intramuscular injections, excessive prior use, or trauma, tend to be most severely involved and have the worst prognosis for recovery (provocation paralysis).

Treatment & Prognosis

Therapy is supportive. Bed rest, fever and pain control (heat therapy is helpful), and careful attention to progression of weakness (particularly of respiratory muscles) are important. No intramuscular injections should be given during the acute phase. Intubation or tracheostomy for secretion control and catheter drainage of the bladder may be needed. Assisted ventilation and enteral feeding may also be needed. Disease is worse in adults and pregnant women than in children. Postpolio muscular atrophy occurs in 30%–40% of paralyzed...
limbs 20–30 years later, characterized by increasing weakness and fasciculations in previously affected, partially recovered limbs.

2. Nonpolio Viral Meningitis

Nonpolio enteroviruses cause over 80% of cases of aseptic meningitis at all ages. In the summer and fall, cases may be seen associated with circulation of multiple neurotropic strains. Nosocomial outbreaks also occur.

Clinical Findings

The usual enteroviral incubation period is 4–6 days. Because many enteroviral infections are subclinical or not associated with central nervous system (CNS) symptoms, a history of contact with a patient with meningitis is unusual. Neonates may acquire infection from maternal blood, vaginal secretions, or feces at birth; occasionally the mother has had a febrile illness just prior to delivery.

A. Symptoms and Signs

Incidence is much greater in children younger than age 1 year. Onset is usually acute with variable fever, marked irritability, and lethargy in infants. Older children also describe frontal headache, photophobia, and myalgia. Abdominal pain, diarrhea, and vomiting may occur. The incidence of rash varies with the infecting strain. If rash occurs, it is usually seen after several days of illness and is diffuse, macular or maculopapular, occasionally petechial, but not purpuric. Oropharyngeal vesicles and rash on the palms and soles suggest an enterovirus. The anterior fontanelle may be full. Meningismus may be present. The illness may be biphasic, with nonspecific symptoms and signs preceding those related to the CNS. In older children, it is easier to demonstrate meningeal signs. Seizures are unusual, and focal neurologic findings, which are rare, should lead to a search for an alternative cause. Frank encephalitis, which is uncommon at any age, occurs most often in neonates. Because of the overall frequency of enteroviral disease in children, 5%–10% of all cases of encephalitis of proved viral origin are caused by enteroviruses. Enteroviruses tend to cause less severe encephalitis than other viral agents. However, parechoviruses, which have recently been demonstrated to be a significant cause of aseptic meningitis, sometimes cause white matter defects.

Enterovirus 71 infections that begin with typical mucocutaneous manifestations of enteroviruses can be complicated by severe brainstem encephalitis and polio-like flaccid paralysis. Enterovirus 70 outbreaks have resulted in hemorrhagic conjunctivitis together with paralytic poliomyelitis. Other nonpolio enteroviruses cause sporadic cases of acute motor weakness similar to that seen with poliovirus infection. Children with congenital immune deficiency, especially agammaglobulinemia, are subject to chronic enteroviral meningoencephalitis that is often fatal or associated with severe sequelae.

B. Laboratory Findings

Blood leukocyte counts are often normal. The spinal fluid leukocyte count is 100–1000/μL. Early in the illness, polymorphonuclear cells predominate; a shift to mononuclear cells occurs within 8–36 hours. In about 95% of cases, spinal fluid parameters include a total leukocyte count less than 3000/μL, protein less than 80 mg/dL, and glucose more than 60% of serum values. Marked deviation from any of these findings should prompt consideration of another diagnosis (see following section). The syndrome of inappropriate secretion of antidiuretic hormone may occur, but is rarely clinically significant.

Culture of CSF may yield an enterovirus within a few days (< 70%). However, PCR for enteroviruses is the most useful diagnostic method in many centers (sensitivity > 90%) and can give an answer within 24–48 hours. Parechoviruses will be detected by most PCR methods, but will be identified as “enterovirus.” Virus may be detected in acellular CSF. Detection of an enterovirus from throat or stool suggests, but does not prove, enteroviral meningitis. Vaccine-strain poliovirus present in feces in infants being evaluated for aseptic meningitis (outside of the United States) may confuse the diagnosis, but can usually be distinguished by growth characteristics.

C. Imaging

Cerebral imaging is not often indicated; if done, it is usually normal. Subdural effusions, infarcts, edema, or focal abnormalities seen in bacterial meningitis are absent except for the rare case of focal encephalitis.

Differential Diagnosis

The leading cause of aseptic meningitis is enteroviruses, especially in the summer and fall. Other causative viruses are mosquito-borne viruses (flavivirus, bunyavirus). These are usually considered during an investigation of encephalitis, but many of them are more likely to cause isolated meningitis and should be considered when seasonal clusters of viral meningitis occur. Primary herpes simplex infection can cause aseptic meningitis in adolescents who have a genital herpes infection. In neonates, early herpes simplex meningoencephalitis may mimic enteroviral disease (see section on Infections due to Herpesviruses). This is an important alternative diagnosis to exclude because of the need for urgent antiviral therapy. Lymphocytic choriomeningitis virus causes meningitis in children in contact with rodents (pet or environmental exposure). Meningitis occurs in some patients...
at the time of infection with human immunodeficiency virus (HIV).

Other causes of aseptic meningitis that may resemble entroviral infection include partially treated bacterial meningitis (recent antibiotic treatment, CSF parameters resembling those seen in bacterial disease and bacterial antigen sometimes present); parameningeal foci of bacterial infection such as brain abscess, subdural empyema, mastoiditis (predisposing factors, glucose level in CSF may be lower, focal neurologic signs, and characteristic imaging); tumors or cysts (malignant cells detected by cytologic examination, a history of neurologic symptoms, higher protein concentration or lower glucose level in CSF); trauma (presence, without exception, of red blood cells, which may be erroneously assumed to be due to traumatic lumbar puncture, but are crenated and fail to clear); vasculitis (other systemic or neurologic signs, found in older children); tuberculous or fungal meningitis (see Chapters 42 and 43); cysticercosis; parainfectious encephalopathies (M pneumoniae, cat-scratch disease, respiratory viruses [especially influenza]); Lyme disease; leptospirosis; and rickettsial diseases.

**Prevention & Treatment**

No specific therapy exists. Infants are usually hospitalized, isolated, and treated with fluids and antipyretics. Moderately to severely ill infants are given appropriate antibiotics for bacterial pathogens until cultures are negative for 48–72 hours. This practice is changing, and hospital stay shortened, in areas where the PCR assay for enteroviruses is available. If patients, especially older children, are mildly ill, antibiotics may be withheld and the child observed. The illness usually lasts less than 1 week. Codeine compounds or other strong analgesics may be needed. C-reactive protein and lactate levels are usually low in the CSF of children with viril meningitis; both may be elevated with bacterial infection. With clinical deterioration, repeat lumbar puncture, cerebral imaging, neurologic consultation, and more aggressive diagnostic tests should be considered. Herpesvirus encephalitis is an important consideration in such cases, particularly in infants younger than age 1 month, and often warrants empiric acyclovir therapy until an etiologic diagnosis is made.

**Prognosis**

In general, entroviral meningitis has no significant short-term neurologic or developmental sequelae. Developmental delay may follow severe neonatal infections. Unlike mumps, enterovirus infections rarely cause hearing loss.

Clinical Findings

A. Symptoms and Signs

1. Gingivostomatitis—High fever, irritability, and drooling occur in infants. Multiple oral ulcers are seen on the tongue and on the buccal and gingival mucosa, occasionally extending to the pharynx. Pharyngeal ulcers may predominate in older children and adolescents. Diffusely swollen red gums that are friable and bleed easily are typical. Cervical nodes are swollen and tender. Duration is 7–14 days. Herpangina, aphthous stomatitis, thrush, and Vincent angina should be excluded.

2. Vulvovaginitis or urethritis (See Chapter 44)—Genital herpes (especially HSV-2) in a prepubertal child should suggest sexual abuse. Vesicles or painful ulcers on the vulva, vagina, or penis, and tender adenopathy are seen. Systemic symptoms (fever, flulike illness, myalgia) are common with the initial episode. Painful urination is frequent, especially in females. Primary infection lasts 10–14 days before healing. Lesions may resemble trauma, syphilis (ulcers are painless), or chancroid (ulcers are painful and nodes are erythematous and fluctuant) in the adolescent, and bullous impetigo or severe chemical irritation in younger children.

3. Cutaneous infections—Direct inoculation onto cuts or abrasions may produce localized vesicles or ulcers. A deep HSV infection on the finger (called herpetic whitlow) may be mistaken for a bacterial felon or paronychia; surgical drainage is of no value and is contraindicated. HSV infection of eczematous skin may result in extensive areas of vesicles and shallow ulcers (eczema herpeticum), which may be mistaken for impetigo or severe chemical irritation in younger children.

4. Recurrent mucocutaneous infection—Recurrent oral shedding is asymptomatic. Perioral recurrences often begin with a prodrome of tingling or burning limited to the vermilion border, followed by vesiculation, scabbing, and crusting around the lips over 3–5 days. Recurrent intraoral lesions are rare. Fever, adenopathy, and other symptoms are absent. Recurrent cutaneous herpes most closely resembles impetigo, but the latter is often outside the perinasal and perioral region, recurs infrequently in the same area of skin, responds to antibiotics, yields a positive result on Gram stain, and Streptococcus pyogenes or Staphylococcus aureus can be isolated. Recurrent genital disease is common after the initial infection with HSV-2. It is shorter (5–7 days) and milder (mean, four lesions) than primary infection and is not associated with systemic symptoms. Recurrent genital disease, which may also recur on the thighs and buttocks, is also preceded by a cutaneous sensory prodrome. Recurrence of HSV-1 in the genital region is much less common than occurs after HSV-2 infection.

5. Keratoconjunctivitis—Keratoconjunctivitis may be part of a primary infection due to spread from infected saliva. Most cases are caused by reactivation of virus latent in the ciliary ganglion. Keratoconjunctivitis produces photophobia, pain, and conjunctival irritation. With recurrences, dendritic corneal ulcers may be demonstrable with fluorescein staining. Stromal invasion may occur. Corticosteroids should never be used for unilateral keratitis without ophthalmologic consultation. Other causes of these symptoms include trauma, bacterial infections, and other viral infections (especially adenovirus if pharyngitis is present; bilateral involvement makes HSV unlikely) (see Chapter 16).

6. Encephalitis—Although unusual in infants outside the neonatal period, encephalitis may occur at any age, usually without cutaneous herpes lesions. In older children, HSV encephalitis can follow a primary infection, but often represents reactivation of latent virus. HSV is the most common cause of sporadic severe encephalitis. Diagnosing this cause of encephalitis is very important because it can be treated with specific antiviral therapy. Acute onset is associated with fever, headache, behavioral changes, and focal neurologic deficits and/or focal seizures. Mononuclear pleocytosis is typically present along with an elevated protein concentration, which continues to rise on repeat lumbar punctures. In older children, hypodense areas with a medial and inferior temporal lobe predilection are seen on CT scan, especially after 3–5 days, but the findings in infants may be more diffuse. Magnetic resonance imaging (MRI) is more sensitive and is positive sooner. Periodic focal epileptiform discharges are seen on electroencephalograms, but are not diagnostic of HSV infection. Viral cultures of CSF are rarely positive. The PCR assay to detect HSV DNA in CSF is a sensitive and specific rapid test. Without early antiviral therapy, the prognosis is poor. The differential diagnosis includes mumps, mosquito-borne and other viral encephalitides, parainfectious and postinfectious encephalopathy, brain abscess, acute demyelinating syndromes, and bacterial meningoencephalitis.

7. Neonatal infections—Infection is occasionally acquired by ascending spread prior to delivery (< 5% of cases), but most often occurs at the time of vaginal delivery from a mother with genital infection. Eight to fifteen percent of HSV-2-seropositive pregnant women at delivery have HSV-2 detected by PCR in the genital tract. However, in most cases this represents reactivation of infection acquired in the distant past. Neonatal infection is rarely acquired from mothers with reactivation disease, whereas it is frequently acquired during delivery of mothers with current or very recent primary infection. This is because transplacentally acquired antibody is usually protective. Occasionally, the infection is acquired in the postpartum period from oral secretions of family members or hospital personnel. A history of genital herpes in the mother may be absent. Within a few days and up to 6 weeks (most often within 4 weeks), skin vesicles appear (especially at sites of trauma, such as...
where scalp monitors were placed). Some infants (45%) have infection limited to the skin, eye, or mouth. Other infants are acutely ill, presenting with jaundice, shock, bleeding, or respiratory distress (20%). Some infants appear well initially, but dissemination of the infection to the brain or other organs becomes evident during the ensuing week. HSV infection (and empiric therapy) should be strongly considered in newborns with the sepsis syndrome that is unresponsive to antibiotic therapy and has negative bacterial cultures. Some infected infants exhibit only neurologic symptoms at 2–3 weeks after delivery: apnea, lethargy, fever, poor feeding, or persistent seizures. The brain infection in these children is often diffuse and is best diagnosed by MRI. The skin lesions may resemble impetigo, bacterial scalp abscesses, or miliaria. Skin lesions may be absent at the time of presentation or may never develop. Skin lesions may recur over weeks or months after recovery from the acute illness. Progressive culture–negative pneumonitis is another manifestation of neonatal HSV. Most cases of neonatal herpes infection are acquired from mothers with undiagnosed genital herpes, most of whom acquired the infection during the pregnancy—especially near term.

**B. Laboratory Findings**

With multisystem disease, abnormalities in platelets, clotting factors, and liver function tests are often present. A finding of lymphocytic pleocytosis and elevated CSF protein indicates viral meningitis or encephalitis. Virus may be cultured from infected epithelial sites (vesicles, ulcers, or conjunctival scrapings). Cultures of CSF yield positive results in about 50% of neonatal cases, but are uncommon in older children. HSV will be detected within 2 days by rapid tissue culture methods, but PCR is the preferred diagnostic method for all specimens. A positive test from skin, throat, eye, or stool of a newborn is diagnostic. Vaginal culture of the mother may offer circumstantial evidence for the diagnosis, but may be negative. Rapid diagnostic tests include immunofluorescent stains or ELISA to detect viral antigen in skin or mucosal scrapings. The PCR assay for HSV DNA is positive (> 95%) in the CSF when there is brain involvement. Serum is often positive in the presence of multisystem disease. Typing of genital HSV isolates from adolescents has prognostic value, since HSV-1 genital infection recurs much less frequently than genital HSV-2 infection.

**Complications, Sequelae, & Prognosis**

Gingivostomatitis may result in dehydration due to dysphagia; severe chronic oral disease and esophageal involvement may occur in immunosuppressed patients. Primary vulvovaginitis may be associated with aseptic meningitis, paresthesias, autonomic dysfunction due to neuritis (urinary retention, constipation), and secondary candidal infection. HIV transmission from individuals who are also seropositive for HSV infection is facilitated, and HIV acquisition is enhanced in HSV-infected contacts. Extensive cutaneous disease (as in eczema) may be associated with dissemination and bacterial superinfection. Keratitis may result in corneal opacification or perforation. Untreated encephalitis is fatal in 70% of patients and causes severe damage in most of the remainder. When acyclovir treatment is instituted early, 20% of patients die and 40% are neurologically impaired.

Disseminated neonatal infection (25% of cases) is fatal for 30% of neonates in spite of therapy, and 20% of survivors are often impaired. Infants with CNS infection (30% of cases) have a 5% mortality with therapy and 70% of survivors are impaired; treated neonates with infection limited to skin, eye, and mouth survive, most often without sequelae.

**Treatment**

**A. Specific Measures**

HSV is sensitive to antiviral therapy.

1. **Topical antivirals**—Antiviral agents are effective for cutaneous and mucocutaneous infections and include 1% trifluridine and 3% acyclovir (1–2 drops five times daily). These agents should be used with the guidance of an ophthalmologist and used concurrently with oral antiviral therapy. They are inferior to oral formulations for treating mucocutaneous and genital infections.

2. **Mucocutaneous HSV infections**—These infections respond to administration of oral nucleoside analogues (acyclovir, valacyclovir, or famciclovir). The main indications are severe genital HSV infection in adolescents (see Chapter 44; acyclovir, 400 mg three times daily for 7–10 days) and severe gingivostomatitis in young children. Antiviral therapy is beneficial for primary disease when begun early. Recurrent disease rarely requires therapy. Frequent genital recurrences may be suppressed by oral administration of nucleoside analogues (acyclovir, 400 mg twice daily), but this approach should be used sparingly. Other forms of severe cutaneous disease, such as eczema herpeticum, respond to these antivirals. Intravenous acyclovir may be required when disease is extensive in immunocompromised children (10–15 mg/kg or 500 mg/m² every 8 hours for 14–21 days). Oral acyclovir, which is available in suspension, is also used within 72–96 hours for severe primary gingivostomatitis in immunocompetent young children (20 mg/kg per dose [maximum of 400 mg per dose] four times a day for 7 days). Antiviral therapy does not alter the incidence or severity of subsequent recurrences of oral or genital infection. Development of resistance to antivirals, which is very rare after treating immunocompetent patients, occurs in immunocompromised patients who receive frequent and prolonged therapy.

3. **Encephalitis**—Treatment consists of intravenous acyclovir, 20 mg/kg (500 mg/m²) every 8 hours for 21 days.
4. Neonatal infection—Newborns receive intravenous acyclovir, 20 mg/kg every 8 hours for 21 days (14 days if infection is limited to skin, eye, or mouth). Therapy should not be discontinued in neonates with CNS disease unless a repeat CSF HSV PCR assay is negative near the end of treatment. The outcome at one year is improved in infants that receive oral acyclovir (300 mg/m²/dose three times daily) for 6 months after completion of IV therapy.

B. General Measures

1. Gingivostomatitis—Gingivostomatitis is treated with pain relief and temperature control measures. Maintaining hydration is important because of the long duration of illness (7–14 days). Nonacidic, cool fluids are best. Topical anesthetic agents (eg, viscous lidocaine or an equal mixture of kaolin–attapulgite [Kaopectate], diphenhydramine, and viscous lidocaine) may be used as a mouthwash for older children who will not swallow it; ingested lidocaine may be toxic to infants or may lead to aspiration. Antiviral therapy is indicated in normal hosts with severe disease. Antibiotics are not helpful.

2. Genital infections—Genital infections may require pain relief, assistance with voiding (warm baths, topical anesthetics, rarely catheterization), and psychological support. Lesions should be kept clean; drying may shorten the duration of symptoms. Sexual contact should be avoided during the interval from prodrome to crusting stages. Because of the frequency of asymptomatic shedding, the only effective way to prevent spread is the use of condoms. Candidal superinfection occurs in 10% of women with primary genital infections.

3. Cutaneous lesions—Skin lesions should be kept clean, dry, and covered if possible to prevent spread. Systemic analgesics may be helpful. Secondary bacterial infection is uncommon in patients with lesions on the mucosa or involving small areas. Secondary infection should be considered and treated if necessary (usually with an antistaphylococcal agent) in patients with more extensive lesions.

4. Recurrent cutaneous disease—Recurrent disease is usually milder than primary infection. Sun block lip balm helps prevent labial recurrences that follow intense sun exposure. There is no evidence that the many popular topical or vitamin therapies are efficacious.

5. Keratoconjunctivitis—An ophthalmologist should be consulted regarding the use of cycloplegics, anti-inflammatory agents, local debridement, and other therapies.

6. Encephalitis—Extensive support will be required for obtunded or comatose patients. Rehabilitation and psychological support are often needed for survivors.

7. Neonatal infection—The affected infant should be isolated and given acyclovir. Cesarean delivery is indicated if the mother has obvious cervical or vaginal lesions, especially if these represent primary infection (35%–50% transmission rate). With infants born vaginally to mothers who have active lesions of recurrent genital herpes, appropriate cultures should be obtained at 24–48 hours after birth, and the infant should be observed closely. Treatment is given to infants whose culture results are positive or who have suggestive signs or symptoms. Infants born to mothers with obvious primary genital herpes should receive therapy before the culture results are known. For women with a history of genital herpes infection, but no genital lesions, vaginal delivery with peripartum cultures of maternal cervix is the standard. Clinical follow-up of the newborn is recommended when maternal culture results are positive. Repeated cervical cultures during pregnancy are not useful.

A challenging problem is the newborn, especially in the first 3 weeks of life, that presents with fever (or hypothermia) and a sepsis-like picture. This is further confounded in the late summer by the existence of circulating enteroviruses. These infants should be considered for empiric acyclovir therapy, pending results of PCR studies, given the poor outcome of disseminated herpes in the newborn. The index of suspicion is increased when there is a CSF pleocytosis, elevated hepatic transaminase levels, a very ill-appearing infant, rash, or respiratory distress.

VARICELLA & HERPES ZOSTER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Varicella (chickenpox):
  - Exposure to varicella or herpes zoster 10–21 days previously; no prior history of varicella.
  - Widely scattered red macules and papules concentrated on the face and trunk, rapidly progressing to clear vesicles on an erythematous base, pustules, and then crusts, over 5–6 days.
  - Variable fever and nonspecific systemic symptoms.
Herpes zoster (shingles):
- History of varicella.
- Dermatomal paresthesias and pain prior to eruption (more common in older children).
- Dermatomal distribution of grouped vesicles on an erythematous base.

General Considerations
Primary infection with varicella-zoster virus results in varicella, which generally confers lifelong immunity, but the virus remains latent lifelong in sensory ganglia. Herpes zoster, which represents reactivation of this latent virus, occurs in 30% of individuals at some time in their life. The incidence of herpes zoster is highest in elderly individuals and in immunosuppressed patients, but herpes zoster occurs in immune competent children. Spread of varicella from a close contact is by respiratory secretions or fomites from vesicles or pustules, with an 85% infection rate in susceptible persons. Exposure to herpes zoster is about one-third as likely to cause varicella in a susceptible host. Over 95% of young adults with a history of varicella are immune, as are 90% of native-born Americans who are unaware of having had varicella. Many individuals from tropical or subtropical regions fail to develop varicella in their childhood and remain susceptible through early adulthood. Humans are the only reservoir.

Clinical Findings
Exposure to varicella or herpes zoster has usually occurred 14–16 days previously (range, 10–21 days). Contact may not have been recognized, since the index case of varicella is infectious 1–2 days before rash appears. Although varicella is the most distinctive childhood exanthem, inexperienced observers may mistake other diseases for varicella. A 1- to 3-day prodrome of fever, malaise, respiratory symptoms, and headache may occur, especially in older children. The unilateral, dermatomal vesicular rash and pain of herpes zoster is very distinctive. The preeruptive pain of herpes zoster may last several days and be mistaken for other illnesses.

A. Symptoms and Signs
1. Varicella—The usual case consists of mild systemic symptoms followed by crops of red macules that rapidly become small vesicles with surrounding erythema (described as a “dew drop on a rose petal”), form pustules, become crusted, and then scab over and rarely leave a scar. The rash appears predominantly on the trunk and face. Lesions occur in the scalp, and sometimes in the nose, mouth (where they are nonspecific ulcers), conjunctiva, and vagina. The magnitude of systemic symptoms usually parallels skin involvement. Up to five crops of lesions may be seen. New crops usually stop forming after 5–7 days. Pruritus is often intense. If varicella occurs in the first few months of life, it is often mild as a result of transplacentally acquired maternal antibody. Once crusting begins, the patient is no longer contagious. A modified form of varicella occurs in about 15% of vaccinated children exposed to varicella, in spite of receiving a single dose of varicella vaccine. This is usually much milder than typical varicella, with fewer lesions that heal rapidly. Cases of modified varicella are contagious, especially if the modified case has 50 or more skin lesions.

2. Herpes zoster (shingles)—This eruption involves a single dermatome (thus unilateral), usually truncal or cranial; occasionally a contiguous dermatome is involved. Especially in older children this is preceded by neuropathic pain or itching in the same area (designated the “prodrome”). The rash does not cross the midline. Ophthalmic zoster may be associated with corneal involvement. The closely grouped vesicles, which resemble a localized version of varicella or herpes simplex, often coalesce. Crusting occurs in 7–10 days. Postherpetic neuralgia is rare in children. A few vesicles are occasionally seen outside the involved dermatome. Herpes zoster is a common problem in HIV-infected or other immunocompromised children, and is also common in children who had varicella in early infancy (< 1–2 years old) or whose mothers had varicella during pregnancy.

B. Laboratory Findings
Leukocyte counts are normal or low. Leukocytosis suggests secondary bacterial infection. The virus can be identified by fluorescent antibody staining of a lesion smear. Rapid culture methods take 48 hours. When the etiology is critical, as in immune compromised children with atypical disease, PCR is definitive. Diagnosis made with paired serology is not clinically useful. Serum aminotransferase levels may be modestly elevated during typical varicella.

C. Imaging
Varicella pneumonia classically produces numerous bilateral nodular densities and hyperinflation. This is very rare in immunocompetent children. Abnormal chest radiographs are seen more frequently in adults and immunocompromised children.

Differential Diagnosis
Varicella is usually distinctive. Similar rashes include those of coxsackievirus infection (fewer lesions, lack of crusting), impetigo (fewer lesions, smaller area, no classic vesicles, positive Gram stain, perioral or peripheral lesions), papular urticaria (insect bite history, nonvesicular rash), scabies (burrows, no typical vesicles; failure to resolve), parapsoriasis...
Complications & Sequelae

A. Varicella

Secondary bacterial infection with staphylococci or group A streptococci is most common, presenting as impetigo, cellulitis or fasciitis, abscesses, scarlet fever, or sepsis. Bacterial superinfection occurs in 2%–3% of children. Before a vaccine became available, hospitalization rates associated with varicella were 1:750–1:1000 cases in children and 10-fold higher in adults.

Protracted vomiting or a change in sensorium suggests Reye syndrome or encephalitis. Because Reye syndrome usually occurs in patients who are also receiving salicylates, these should be avoided in patients with varicella. Encephalitis occurs in less than 0.1% of cases, usually in the first week of illness, and is usually limited to cerebellitis with ataxia, which resolves completely. Diffuse encephalitis can be severe.

Varicella pneumonia usually afflicts immunocompromised children (especially those with leukemia or lymphoma or those receiving high doses of corticosteroids or chemotherapy) and adults; pregnant women may be at special risk. Cough, dyspnea, tachypnea, rales, and cyanosis occur several days after onset of rash. Varicella may be life-threatening in immunosuppressed patients. In addition to pneumonitis, their disease may be complicated by hepatitis and encephalitis. The acute illness in these children often begins with unexplained severe abdominal pain. Varicella exposure in severely varicella-naïve immunocompromised children must be evaluated immediately for postexposure prophylaxis (see Chapter 10).

Hemorrhagic varicella lesions may be seen without other complications. This is most often caused by autoimmune thrombocytopenia, but hemorrhagic lesions can occasionally represent idiopathic disseminated intravascular coagulation (purpura fulminans).

Neonates born to mothers who develop varicella from 5 days before to 2 days after delivery are at high risk for severe or fatal (5%) disease and must be given varicella-zoster immune globulin (VariZIG) and followed closely (see Chapter 10).

Varicella occurring during the first 20 weeks of pregnancy may cause (2% incidence) congenital infection associated with cicatricial skin lesions, associated limb anomalies, and cortical atrophy.

Unusual complications of varicella include optic neuritis, myocarditis, transverse myelitis, orchitis, and arthritis.

B. Herpes Zoster

Complications of herpes zoster include secondary bacterial infection, motor or cranial nerve paralysis, meningitis, encephalitis, keratitis and other ocular complications, and dissemination in immunosuppressed patients. These complications are rare in immune competent children, and they do not develop prolonged pain. Postherpetic neuralgia does occur in immunocompromised children.

Prevention

Varicella-specific hyperimmune globulin is available for postexposure prevention of varicella of high-risk susceptible persons (see Chapter 10). In immune competent children postexposure prophylaxis with acyclovir is effective when it is started at 7–9 days after exposure and is continued for 7 days, as is varicella vaccine when given within 3–5 days of the exposure.

Two doses of the live attenuated varicella vaccine are now part of routine childhood immunization, and “catch-up” immunization is recommended for all other susceptible children and adults.

Treatment

A. General Measures

Supportive measures include maintenance of hydration, administration of acetaminophen for discomfort, cool soaks or antipruritics for itching (diphenhydramine, 1.25 mg/kg every 6 hours, or hydroxyzine, 0.5 mg/kg every 6 hours), and observance of general hygiene measures (keep nails trimmed and skin clean). Care must be taken to avoid overdosage with antihistaminic agents. Topical or systemic antibiotics may be needed for bacterial superinfection.

B. Specific Measures

Acyclovir is the preferred drug for varicella and herpes zoster infections. Recommended parenteral acyclovir dosage for severe disease is 10 mg/kg (500 mg/m²) intravenously every 8 hours, each dose infused over 1 hour, for 7–10 days. Parenteral therapy should be started early in immunocompromised patients or high-risk infected neonates. Hyperimmune globulin is of no value for established disease. The effect of oral acyclovir (80 mg/kg/d, divided in four doses) on varicella in immunocompetent children was modestly beneficial and nontoxic, but only when administered within 24 hour after the onset of varicella. Oral acyclovir should be used selectively in immunocompetent children (eg, when intercurrent illness is present; possibly when the index case is a sibling or when the patient is an adolescent—both of which are associated with more severe disease) and in children with underlying chronic illnesses. Valacyclovir and famciclovir are superior antiviral agents.
because of better absorption; only acyclovir and valacyclovir are available as a pediatric suspension. Herpes zoster in an immunocompromised child should be treated with intravenous acyclovir when it is severe, but oral valacyclovir or famciclovir can be used in immunocompromised children when the nature of the illness and the immune status support this decision.

**Prognosis**

Except for secondary bacterial infections, serious complications are rare and recovery complete in immune competent hosts.

**ROSEOLA INFANTUM (EXANThem SUBITUM)**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- High fever in a child aged 6–36 months.
- Minimal toxicity.
- Rose-pink maculopapular rash appears when fever subsides.

**General Considerations**

Roseola infantum is a benign illness caused by HHV-6 or HHV-7. HHV-6 is a major cause of acute febrile illness in young children. Its significance is that it may be confused with more serious causes of high fever and its role in inciting febrile seizures.

**Clinical Findings**

The most prominent historical feature is the abrupt onset of fever, often reaching 40.6°C, which lasts up to 8 days (mean, 4 days) in an otherwise mildly ill child. The fever then ceases abruptly, and a characteristic rash may appear. Roseola occurs predominantly in children aged 6 months to 3 years, with 90% of cases occurring before the second year. HHV-7 infection tends to occur somewhat later in childhood. These viruses are the most common recognized cause of exanthematous fever in this age group and are responsible for 20% of emergency department visits by children aged 6–12 months.

**A. Symptoms and Signs**

Mild lethargy and irritability may be present, but generally there is a dissociation between other systemic symptoms and the febrile course. The pharynx, tonsils, and tympanic membranes may be injected. Conjunctivitis and pharyngeal exudate are notably absent. Diarrhea and vomiting occur in one-third of patients. Adenopathy of the head and neck often occurs. The anterior fontanelle is bulging in one-quarter of HHV-6–infected infants. If rash appears (20%–30% incidence), it coincides with lysis of fever and begins on the trunk and spreads to the face, neck, and extremities. Rose-pink macules or maculopapules, 2–3 mm in diameter, are nonpruritic, tend to coalesce, and disappear in 1–2 days without pigmentation or desquamation. Rash may occur without fever.

**B. Laboratory Findings**

Leukopenia and lymphocytopenia are present early. Laboratory evidence of hepatitis occurs in some patients, especially adults.

**Differential Diagnosis**

The initial high fever may require exclusion of serious bacterial infection. The relative well-being of most children and the typical course and rash soon clarify the diagnosis. The erythrocyte sedimentation rate is normal. If the child has a febrile seizure, it is important to exclude bacterial meningitis. The CSF is normal in children with roseola. In children who receive antibiotics or other medication at the beginning of the fever, the rash may be attributed incorrectly to drug allergy.

**Complications & Sequelae**

Febrile seizures occur in up to 10% of patients (even higher percentages in those with HHV-7 infections). There is evidence that HHV-6 can directly infect the CNS, causing meningoencephalitis or aseptic meningitis. Multiorgan disease (pneumonia, hepatitis, bone marrow suppression, encephalitis) may occur in immunocompromised patients.

**Treatment & Prognosis**

Fever is managed readily with acetaminophen and sponge baths. Fever control should be a major consideration in children with a history of febrile seizures. Roseola infantum is otherwise entirely benign.

Primary infection:
• Asymptomatic or minor illness in young children.
• Mononucleosis-like syndrome without pharyngitis in postpubertal individuals.

Congenital infection:
• Intrauterine growth retardation.
• Microcephaly with intracerebral calcifications and seizures.
• Retinitis and encephalitis.
• Hepatosplenomegaly with thrombocytopenia.
• “Blueberry muffin” rash.
• Sensorineural deafness.

Immunocompromised hosts:
• Retinitis and encephalitis.
• Pneumonitis.
• Enteritis and hepatitis.
• Bone marrow suppression.

General Considerations
Cytomegalovirus (CMV) is a ubiquitous herpesvirus transmitted by many routes. It can be acquired in utero following maternal viremia or postpartum from birth canal secretions or maternal milk. Young children are infected by the saliva of playmates; older individuals are infected by sexual partners (eg, from saliva, vaginal secretions, or semen). Transfused blood products and transplanted organs can be a source of CMV infection. Clinical illness is determined largely by the patient’s immune competence. Immunocompetent individuals usually develop a mild self-limited illness, whereas immunocompromised children can develop severe, progressive, often multiorgan disease. In utero infection can be teratogenic.

1. In Utero Cytomegalovirus Infection
Approximately 0.5%–1.5% of children are born with CMV infections acquired during maternal viremia or postpartum from birth canal secretions or maternal milk. Young children are infected by the saliva of playmates; older individuals are infected by sexual partners (eg, from saliva, vaginal secretions, or semen). Transfused blood products and transplanted organs can be a source of CMV infection. Clinical illness is determined largely by the patient’s immune competence. Immunocompetent individuals usually develop a mild self-limited illness, whereas immunocompromised children can develop severe, progressive, often multiorgan disease. In utero infection can be teratogenic.

Clinical Findings
A. Symptoms and Signs
Severely affected infants are born ill; they are often small for gestational age, floppy, and lethargic. They feed poorly and have poor temperature control. Hepatosplenomegaly, jaundice, petechiae, seizures, and microcephaly are common. Characteristic signs are a distinctive chorioretinitis and periventricular calcification. A purpuric (so-called blueberry muffin) rash similar to that seen with congenital rubella may be present. The mortality rate is 10%–20%. Survivors usually have significant sequelae, especially mental retardation, neurologic deficits, retinopathy, and hearing loss. Isolated hepatosplenomegaly or thrombocytopenia may occur. Even mildly affected children may subsequently manifest mental retardation and psychomotor delay. However, most infected infants (90%) are born to mothers with preexisting immunity who experienced a reactivation of latent CMV during pregnancy. These children have no clinical manifestations at birth. Of these, 10%–15% develop sensorineural hearing loss, which is often bilateral and may appear several years after birth.

B. Laboratory Findings
In severely ill infants, anemia, thrombocytopenia, hyperbilirubinemia, and elevated aminotransferase levels are common. Lymphocytosis occurs occasionally. Pleocytosis and an elevated protein concentration are found in CSF. The diagnosis is readily confirmed by isolation of CMV from urine or saliva within 48 hours, using rapid culture methods combined with immunoassay. The presence in the infant of IgM-specific CMV antibodies suggests the diagnosis. Some commercial ELISA kits are 90% sensitive and specific for these antibodies. Universal screening of asymptomatic children using blood or saliva CMV PCR during the first weeks of life is useful for early detection of children at high risk of developing hearing loss.

C. Imaging
Head radiologic examinations may show microcephaly, periventricular calcifications, and ventricular dilation. These findings strongly correlate with neurologic sequelae and retardation. Long bone radiographs may show the “celery stalk” pattern characteristic of congenital viral infections. Interstitial pneumonia may be present.

Differential Diagnosis
CMV infection should be considered in any newborn that is seriously ill shortly after birth, especially once bacterial
sepsis, metabolic disease, intracranial bleeding, and cardiac disease have been excluded. Other congenital infections to be considered in the differential diagnosis include toxoplasmosis (serology, more diffuse calcification of the CNS, specific type of retinitis, macrocephaly), rubella (serology, specific type of retinitis, cardiac lesions, eye abnormalities), enteroviral infections (time of year, maternal illness, severe hepatitis, PCR), herpes simplex (skin lesions, cultures, severe hepatitis, PCR), and syphilis (serology for both infant and mother, skin lesions, bone involvement).

**Prevention & Treatment**

Support is rarely required for anemia and thrombocytopenia. Most children with symptoms at birth have significant neurologic, intellectual, visual, or auditory impairment. Ganciclovir, 5 mg/kg every 12 hours, for up to 6 weeks is recommended for children with severe, life- or sight-threatening disease, or if end-organ disease recurs or progresses. Studies are currently ongoing to determine if early and more prolonged treatment (6 months) with valganciclovir decreases the risk or magnitude of hearing loss, which affects 6%–23% of children with asymptomatic CMV at birth. While studies are ongoing, several publications reported anecdotal success of prolonged valganciclovir therapy (32 mg/kg/d in two doses) for 6 months.

Recent developments in the diagnosis of primary CMV infection during pregnancy using anti-CMV IgM and low-avidity IgG assays followed by quantitative CMV PCR testing of the amniotic fluid at 20–24 weeks gestation have made possible the diagnosis of congenital CMV infection before birth. Many pregnant women elect to terminate gestation under these circumstances, but a recent study has also shown that passive immunoprophylaxis with hyperimmune CMV IgG may prevent development of congenital disease. A subunit CMV vaccine administered to CMV-seronegative pregnant women had a 50% efficacy for prevention of congenital CMV infection.

### 2. Perinatal Cytomegalovirus Infection

CMV infection can be acquired from birth canal secretions or shortly after birth from maternal milk. In some socioeconomic groups, 10%–20% of infants are infected at birth and excrete CMV for many months. Infection can also be acquired in the postnatal period from unscreened transfused blood products.

**Clinical Findings**

**A. Symptoms and Signs**

Ninety percent of immunocompetent infants infected by their mothers at birth develop subclinical illness (ie, virus excretion only) or a minor illness within 1–3 months. The remainder develop an illness lasting several weeks characterized by hepatosplenomegaly, lymphadenopathy, and interstitial pneumonitis in various combinations. The severity of the pneumonitis may be increased if there is simultaneous presence of *Chlamydia trachomatis*. Infants who receive blood products are often premature and immunologically impaired. If they are born to CMV-negative mothers and subsequently receive CMV-containing blood, they frequently develop severe infection and pneumonia after a 2- to 6-week incubation period.

**B. Laboratory Findings**

Lymphocytosis, atypical lymphocytes, anemia, and thrombocytopenia may be present, especially in premature infants. Liver function is abnormal. CMV is readily isolated from urine and saliva. Secretions obtained at bronchoscopy contain CMV and epithelial cells bearing CMV antigens. Serum levels of CMV antibody rise significantly.

**C. Imaging**

Chest radiographs show a diffuse interstitial pneumonitis in severely affected infants.

**Differential Diagnosis**

CMV infection should be considered as a cause of any prolonged illness in early infancy, especially if hepatosplenomegaly, lymphadenopathy, or atypical lymphocytosis is present. This must be distinguished from granulomatous or malignant diseases and from congenital infections (syphilis, toxoplasmosis, hepatitis B, HIV) not previously diagnosed. Other viruses (Epstein-Barr virus [EBV], HIV, adenovirus) can cause this syndrome. CMV is a recognized cause of viral pneumonia in this age group. Because asymptomatic CMV excretion is common in early infancy, care must be taken to establish the diagnosis and to rule out concomitant pathogens such as *Chlamydia* and RSV. Severe CMV infection in early infancy may indicate that the child has a congenital or acquired immune deficiency.

**Prevention & Treatment**

The self-limited disease of normal infants requires no therapy. Severe pneumonitis in premature infants requires oxygen administration and often intubation. Very ill infants should receive ganciclovir (6 mg/kg every 12 hours). CMV infection acquired by transfusion can be prevented by excluding CMV-seropositive blood donors. Milk donors should also be screened for prior CMV infection. It is likely that high-risk infants receiving large doses of IVIG for other reasons will be protected against severe CMV disease.
3. Cytomegalovirus Infection Acquired in Childhood & Adolescence

Young children are readily infected by playmates, especially because CMV continues to be excreted in saliva and urine for many months after infection. The cumulative annual incidence of CMV excretion by children in day care centers exceeds 75%. In fact, young children in a family are often the source of primary CMV infection of their mothers during subsequent pregnancies. An additional peak of CMV infection takes place when adolescents become sexually active. Sporadic acquisition of CMV occurs after blood transfusion and transplantation.

Clinical Findings
A. Symptoms and Signs
Most young children who acquire CMV are asymptomatic or have a minor febrile illness, occasionally with adenopathy. They provide an important reservoir of virus shedders that facilitates spread of CMV. Occasionally a child may have prolonged fever with hepatosplenomegaly and adenopathy. Older children and adults, many of whom are infected during sexual activity, are more likely to be symptomatic in this fashion and can present with a syndrome that mimics the infectious mononucleosis syndrome that follows EBV infection (1–2 weeks of fever, malaise, anorexia, splenomegaly, mild hepatitis, and some adenopathy; see next section). This syndrome can also occur 2–4 weeks after transfusion of CMV-infected blood.

B. Laboratory Findings
In the CMV mononucleosis syndrome, lymphocytosis and atypical lymphocytes are common, as is a mild rise in amino-transferase levels. CMV is present in saliva and urine; CMV DNA can be uniformly detected in plasma or blood.

Differential Diagnosis
In older children, CMV infection should be included as a possible cause of fever of unknown origin, especially when lymphocytosis and atypical lymphocytes are present. CMV infection is distinguished from EBV infection by the absence of pharyngitis, the relatively minor adenopathy, and the absence of serologic evidence of acute EBV infection. Mononucleosis syndromes also are caused by Toxoplasma gondii, rubella virus, adenovirus, hepatitis A virus, and HIV.

Prevention
Screening of transfused blood or filtering blood (thus removing CMV-containing white blood cells) prevents cases related to this source.

4. Cytomegalovirus Infection in Immunocompromised Children

In addition to symptoms experienced during primary infection, immunocompromised hosts develop symptoms with reinfec tion or reactivation of latent CMV. This is clearly seen in children with acquired immunodeficiency syndrome (AIDS), after transplantation, or with congenital immunodeficiencies. However, in most immunocompromised patients, primary infection is more likely to cause severe symptoms than is reactivation or reinfection. The severity of the resulting disease is generally proportionate to the degree of immunosuppression.

Clinical Findings
A. Symptoms and Signs
A mild febrile illness with myalgia, malaise, and arthralgia may occur, especially with reactivation disease. Severe disease often includes subacute onset of dyspnea and cyanosis as manifestations of interstitial pneumonitis. Auscultation reveals only coarse breath sounds and scattered rales. A rapid respiratory rate may precede clinical or radiographic evidence of pneumonia. Hepatitis without jaundice or hepatomegaly is common. Diarrhea, which can be severe, occurs with CMV colitis, and CMV can cause esophagitis with symptoms of odynophagia or dysphagia. These enteropathies are most common in AIDS, as is the presence of a retinitis that often progresses to blindness. Encephalitis and polyradiculitis also occur in AIDS.

B. Laboratory Findings
Neutropenia and thrombocytopenia are common. Atypical lymphocytosis is infrequent. Serum aminotransferase levels are often elevated. The stools may contain occult blood if enteropathy is present. CMV is readily isolated from saliva, urine, buffy coat, and bronchial secretions. Results are available in 48 hours. Interpretation of positive cultures is made difficult by asymptomatic shedding of CMV in saliva and urine in many immunocompromised patients. CMV disease correlates more closely with the presence of CMV in the blood or lung lavage fluid. Monitoring for the appearance of CMV DNA in plasma or CMV antigen in blood mononuclear cells is used as a guide to early antiviral (“preemptive”) therapy.

C. Imaging
Bilateral interstitial pneumonitis is present on chest radiographs.

Differential Diagnosis
The initial febrile illness must be distinguished from treatable bacterial or fungal infection. Similarly, the pulmonary...
disease must be distinguished from intrapulmonary hemorrhage; drug-induced or radiation pneumonitis; pulmonary edema; and bacterial, fungal, parasitic, and other virus infections. CMV infection causes bilateral and interstitial abnormalities on chest radiographs, cough is nonproductive, chest pain is absent, and the patient is not usually toxic. *Pneumocystis jiroveci* infection may have a similar presentation. These patients may have polymicrobial disease. It is suspected that bacterial and fungal infections are enhanced by the neutropenia that can accompany CMV infection. Infection of the gastrointestinal tract is diagnosed by endoscopy. This will exclude candidal, adenoviral, and herpes simplex infections and allows tissue confirmation of CMV-induced mucosal ulcerations.

**Prevention & Treatment**

Blood donors should be screened to exclude those with prior CMV infection, or blood should be filtered. Ideally, seronegative transplant recipients should receive organs from seronegative donors. Severe symptoms, most commonly pneumonitis, often respond to early therapy with intravenous ganciclovir (5 mg/kg every 12 hours for 14–21 days). Neutropenia is a frequent side effect of this therapy. Foscarnet and cidofovir are alternative therapeutic agents recommended for patients with ganciclovir-resistant virus. Prophylactic use of oral or intravenous ganciclovir or foscarnet may prevent CMV infections in organ transplant recipients. Preemptive therapy can be used in transplant recipients by monitoring CMV in blood by PCR and instituting therapy when the results reach a certain threshold regardless of clinical signs or symptoms.

**General Considerations**

Mononucleosis is the most characteristic syndrome produced by EBV infection. Young children infected with EBV have either no symptoms or a mild nonspecific febrile illness. As the age of the host increases, EBV infection is more likely to produce the typical features of the mononucleosis syndrome, including 20%–25% of infected adolescents. EBV is acquired readily from asymptomatic carriers (15%–20% of whom excrete the virus in saliva on any given day) and from recently ill patients, who excrete virus for many months. Young children are infected from the saliva of playmates and family members. Adolescents may be infected through sexual activity. EBV can also be transmitted by blood transfusion and organ transplantation.

**Clinical Findings**

**A. Symptoms and Signs**

After an incubation period of 1–2 months, a 2- to 3-day prodrome of malaise and anorexia yields, abruptly or insidiously, to a febrile illness with temperatures exceeding 39°C. The major complaint is pharyngitis, which is often (50%) exudative. Lymph nodes are enlarged, firm, and mildly tender. Any area may be affected, but posterior and anterior cervical nodes are almost always enlarged. Splenomegaly is present in 50%–75% of patients. Hepatomegaly is common (30%), and the liver is frequently tender. Five percent of patients have a rash, which can be macular, scarlatiniform, or urticarial. Rash is almost universal in patients taking penicillin or ampicillin. Soft palate petechiae and eyelid edema are also observed.

**B. Laboratory Findings**

1. **Peripheral blood**—Leukopenia may occur early, but an atypical lymphocytosis (comprising over 10% of the total leukocytes at some time in the illness) is most notable. Hematologic changes may not be seen until the third week of illness and may be entirely absent in some EBV syndromes (eg, neurologic).

2. **Heterophil antibodies**—These nonspecific antibodies appear in over 90% of older patients with mononucleosis, but in fewer than 50% of children younger than age 5 years. They may not be detectable until the second week of illness and may persist for up to 12 months after recovery. Rapid screening tests (slide agglutination) are usually positive if the titer is significant; a positive result strongly suggests but does not prove EBV infection.
3. **Anti-EBV antibodies**—It may be necessary to measure specific antibody titers when heterophile antibodies fail to appear, as in young children. Acute EBV infection is established by detecting IgM antibody to the viral capsid antigen (VCA) or by detecting a fourfold or greater change of IgG anti-VCA titers (in normal hosts, IgG antibody peaks by the time symptoms appear; in immunocompromised hosts, the tempo of antibody production may be delayed). The absence of anti–EBV nuclear antigen (EBNA) antibodies, which are typically first detected at least 4 weeks after the initiation of symptoms, may also be used to diagnose acute infection in immunocompetent hosts. However, immunocompromised hosts may fail to develop anti-EBNA antibodies.

4. **EBV PCR**—Detection of EBV DNA is the method of choice for the diagnosis of CNS and ocular infections. Quantitative EBV PCR in peripheral blood mononuclear cells has been used to diagnose EBV-related lymphoproliferative disorders in transplant patients.

### Differential Diagnosis

Severe pharyngitis may suggest group A streptococcal infection. Enlargement of only the anterior cervical lymph nodes, a neutrophilic leukocytosis, and the absence of splenomegaly suggest bacterial infection. Although a child with a positive throat culture result for *Streptococcus* usually requires therapy, up to 10% of children with mononucleosis are asymptomatic streptococcal carriers. In this group, penicillin therapy is unnecessary and often causes a rash. Severe primary herpes simplex pharyngitis, occurring in adolescence, may also mimic infectious mononucleosis. With herpes simplex pharyngitis, some anterior mouth ulcerations should suggest the correct diagnosis. Adenoviruses are another cause of severe, often exudative pharyngitis. EBV infection should be considered in the differential diagnosis of any perplexing prolonged febrile illness. Similar illnesses that produce atypical lymphocytosis include rubella (pharyngitis not prominent, shorter illness, less adenopathy and splenomegaly), adenovirus (upper respiratory symptoms and cough, conjunctivitis, less adenopathy, fewer atypical lymphocytes), hepatitis A or B (more severe liver function abnormalities, no pharyngitis, no lymphadenopathy), and toxoplasmosis (negative heterophil test, less pharyngitis). Serum sickness–like drug reactions and leukemia (smear morphology is important) may be confused with infectious mononucleosis. CMV mononucleosis is a close mimic except for minimal pharyngitis and less adenopathy; it is much less common. Serologic tests for EBV and CMV should clarify the correct diagnosis. The acute initial manifestation of HIV infection can be a mononucleosis-like syndrome.

### Complications

Splenic rupture is a rare complication, which usually follows significant trauma. Hematologic complications, including hemolytic anemia, thrombocytopenia, and neutropenia, are more common. Neurologic involvement can include aseptic meningitis, encephalitis, isolated neuropathy such as Bell palsy, and Guillain-Barré syndrome. Any of these may appear prior to or in the absence of the more typical signs and symptoms of infectious mononucleosis. Rare complications include myocarditis, pericarditis, and atypical pneumonia. Recurrence or persistence of EBV-associated symptoms for 6 months or longer characterizes chronic active EBV. This disease is due to continuous viral replication and warrants specific antiviral therapy. Rarely EBV infection becomes a progressive lymphoproliferative disorder characterized by persistent fever, multiple organ involvement, neutropenia or pancytopenia, and agammaglobulinemia. Hemicytaphagia is often present in the bone marrow. An X-linked genetic defect in immune response has been inferred for some patients (Duncan syndrome, X-linked lymphoproliferative disorder). Children with other congenital immunodeficiencies or chemotherapy-induced immunosuppression can also develop progressive EBV infection, EBV-associated lymphoproliferative disorder, lymphoma, and other malignancies.

### Treatment & Prognosis

Bed rest may be necessary in severe cases. Acetaminophen controls high fever. Potential airway obstruction due to swollen pharyngeal lymphoid tissue responds rapidly to systemic corticosteroids. Corticosteroids may also be given for hematologic and neurologic complications, although no controlled trials have proved their efficacy in these conditions. Fever and pharyngitis disappear by 10–14 days. Adenopathy and splenomegaly can persist several weeks longer. Some patients complain of fatigue, malaise, or lack of well-being for several months. Although corticosteroids may shorten the duration of fatigue and malaise, their long-term effects on this potentially oncogenic viral infection are unknown, and indiscriminate use is discouraged. Patients with splenic enlargement should avoid contact sports for 6–8 weeks. Acyclovir, valacyclovir, penciclovir, ganciclovir, and foscarnet are active against EBV and are indicated in the treatment of chronic active EBV.

Management of EBV-related lymphoproliferative disorders relies primarily on decreasing the immunosuppression whenever possible. Adjunctive therapy with acyclovir, ganciclovir, or another antiviral active against EBV as well as γ globulin has been used without scientific evidence of efficacy.

In the United States, mosquitoes are the most common insect vectors that spread viral infections (Table 40–4). As a consequence, these infections—and others that are spread by ticks—tend to occur as summer–fall epidemics that coincide with the seasonal breeding and feeding habits of the vector, and the etiologic agent varies by region. Other insect-borne viral infections are seen in international travelers. Thus, a careful travel and exposure history is critical for correct diagnostic workup.

**ENCEPHALITIS**

### ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fever and headache.
- Change in mental status or behavior (or both), with or without focal neurologic deficits.
- CSF shows a mononuclear cell pleocytosis, elevated protein level, and normal glucose level.

Encephalitis is a common severe manifestation of many infections spread by insects (see Table 40–4). With many viral pathogens, the infection is most often subclinical, or a mild CNS disease such as meningitis is present. These infections have some distinguishing features in terms of subclinical infection rate, unique neurologic syndromes, associated systemic symptoms, and prognosis. The diagnosis is generally made clinically during recognized outbreaks and is confirmed by virus-specific serology. Prevention consists of control of mosquito vectors and precautions with proper clothing and insect repellents to minimize mosquito and tick bites. It is essential before making the diagnosis of arboviral encephalitis, which is not treatable, to exclude herpes encephalitis, which warrants specific antiviral therapy. Delay in administering this therapy may have dire consequences.

### West Nile Virus Encephalitis

This flavivirus is the most important arbovirus infection in the United States. In 2003 there were more than 10,000 clinically apparent infections, more than 2900 nervous system infections, and 265 deaths, in 47 states. Prevalence had declined significantly, but in 2012 there was a resurgence to more than 5000 reported cases, of which approximately half were neuroinvasive; 240 were fatal. The reservoir of West Nile virus includes more than 160 species of birds whose migration explains the extent of endemic disease. Epidemics occur in summer–fall; most infected individuals are asymptomatic. Approximately 20% develop West Nile fever, which is characterized by fever, headache, retro-orbital pain, nausea and vomiting, lymphadenopathy, and a maculopapular rash (20%–50%). Less than 1% of infected patients develop meningitis or encephalitis, but 10% of these cases are fatal (0.2% of all infections). Children are most likely to have neuroinvasive disease limited to meningitis. The major risk factor for severe disease is age older than 50 years and immune compromise. Children, especially adolescents, develop West Nile fever; less than one-third of children with clinically apparent infection have neuroinvasive disease. The neurologic manifestations are most often those found with other meningoencephalitides. However, distinguishing atypical features include polio-like flaccid paralysis, movement disorders (parkinsonism, tremor, myoclonus), brainstem symptoms, polyneuropathy, and optic neuritis. Muscle weakness, facial palsy, and hyporeflexia are common (20% of each finding). Recovery is slow and serious sequela occur in some severely affected patients. Diagnosis is best made by detecting IgM antibody (enzyme immunoassay [EIA]) to the virus in CSF. This will be present by 5–6 days (95%) after onset. PCR is a specific diagnostic tool, but is less sensitive than antibody detection. Antibody rise in serum can also be used for diagnosis.

Treatment is supportive, although various antivirals and specific immune globulin are being studied. The infection is not spread between contacts, but can be spread by donated organs, blood, and breast milk, and transplacentally.

### DENGUE

### ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Travel or residence in an endemic area.
- First infection (first episode) results in nonspecific rash and fever; retro-orbital pain, severe myalgia, and arthralgia may occur.
- Subsequent infection with a different (heterotypic) serotype of dengue may result in dengue hemorrhagic fever (thrombocytopenia, bleeding, plasma leak syndrome); this may progress to shock (dengue shock syndrome).
Table 40–4. Some insect-borne viral diseases occurring in the United States or in returning U.S. travelers.

In endemic areas, more than 50 million cases of dengue occur each year, often in severe forms. In the United States, more than 400 cases are diagnosed, most often in travelers from the Caribbean or Asia and less often in those visiting Central and South America, making it the most common arboviral disease in travelers. Dengue is the second most common cause of fever (after malaria) in returning travelers. Dengue occurs in Mexico; Texas and Key West have sporadic indigenous outbreaks and the disease has been epidemic in Puerto Rico. The spread of dengue requires the requisite species (which is present in the United States) of mosquito, which transmits virus from a reservoir of viremic humans in endemic areas. Most patients have mild disease, especially young children, who may have a nonspecific fever and rash. Severity is a function of age, and prior infection with other serotypes of dengue virus is a prerequisite for severe hemorrhagic complications.

Clinical Findings

A. Symptoms and Signs

Dengue fever begins abruptly 4–7 days after transmission (range, 3–14 days) with fever, chills, severe retro-orbital pain, severe muscle and joint pain, nausea, and vomiting. Erythema of the face and torso may occur early. After 3–4 days, a centrifugal maculopapular rash appears in half of the patients. The rash can become petechial, and mild hemorrhagic signs (epistaxis, gingival bleeding, microscopic blood in stool or urine) may be noted. The illness lasts 5–7 days, although rarely fever may reappear for several additional days. Fever may become relatively lower on the third day, only to become higher until defervescence. Since there are four distinct serotypes of dengue virus, multiple sequential infections can occur.

B. Laboratory Findings

Leukopenia and a mild drop in platelets are common. Liver function tests are usually normal. Diagnosis is made by viral culture of plasma (50% sensitive up to the fifth day), detection of viral antigenemia (90% sensitive during the febrile phase of first infections), detection of IgM-specific ELISA antibodies (90% sensitive at the sixth day), or by detecting a rise in type-specific antibody. PCR testing is available for diagnosis in some areas.

Differential Diagnosis

This diagnosis should be considered for any traveler to an endemic area who has symptoms suggestive of a systemic viral illness, although less than 1 in 1000 travelers to these areas develops dengue. Often the areas visited have other unique pathogens circulating (eg, malaria, typhoid fever, leptospirosis, rickettsial diseases, other endemic alphaviruses and flaviviruses, and measles). Especially relevant in travelers from India and the Indian ocean islands is chikungunya fever, which also presents with fever, and rash. This illness is associated with arthralgia/arthritis, rather than myalgia as is seen with dengue. EBV, influenza, enteroviruses, and acute HIV infection may produce a similar illness. Dengue is not associated with sore throat or cough. An illness that starts 2 weeks after the trip ends or that lasts longer than 2 weeks is not dengue or chikungunya fever.

Complications

Rarely dengue fever is associated with meningoencephalitis (5%–10%) or hepatic damage. More common in endemic areas is the appearance of dengue hemorrhagic fever, which is defined by significant thrombocytopenia (< 100,000 platelets/μL, bleeding, and a plasma leak syndrome [hematocrit > 20% higher than baseline], hypoaalbuminemia, and pleural or peritoneal effusions). This occurs most frequently with a second or subsequent attack of dengue, as a consequence of circulating antibody and other immune responses acquired from prior dengue virus infections; thus, it is rarely seen in typical travelers. Failure to recognize and treat this complication may lead to dengue shock syndrome, which is defined by signs of circulatory failure and hypotension or shock, and has a high fatality rate (10%). Dengue can be transmitted in utero from a pregnant woman infected within 2 weeks prior to delivery.

Prevention

Prevention of dengue fever involves avoiding high-risk areas and using conventional mosquito avoidance measures. The main vector is a daytime feeder. Several vaccines to prevent dengue are being tested.

Treatment

Dengue fever is treated by oral replacement of fluid lost from gastrointestinal symptoms. Analgesic therapy, which is often necessary, should not include drugs that affect platelet function. Recovery is complete without sequelae. The hemorrhagic syndrome requires prompt fluid therapy with plasma expanders and isotonic saline.

COLORADO TICK FEVER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Travel in endemic area; tick bite.
- Fever, chills, headache, retro-orbital pain, myalgia.
- Biphasic fever curve.
- Leukopenia early in the illness.

Colorado tick fever is endemic in the high plains and mountains of the central and northern Rocky Mountains and northern Pacific coast of the United States. The reservoir of the virus consists of squirrels and chipmunks. Many hundreds of cases of Colorado tick fever occur each year in visitors or laborers entering this region, primarily from May through July.

Clinical Findings

A. Symptoms and Signs

After a 3- to 4-day incubation period (maximum, 14 days), fever begins suddenly together with chills, lethargy, headache, ocular pain, myalgia, abdominal pain, and nausea and vomiting. Conjunctivitis may be present. A nondistinctive maculopapular rash occurs in 5%-10% of patients. The illness lasts 7–10 days, and half of patients have a biphasic fever curve with several afebrile days in the midst of the illness.

B. Laboratory Findings

Leukopenia is characteristic early in the illness. Platelets are modestly decreased. Specific ELISA testing is available, but 2–3 weeks may elapse before seroconversion. Fluorescent antibody staining will detect virus-infected erythrocytes during the illness and for weeks after recovery. RT-PCR is available in some areas that will be positive within the first week of illness.

Differential Diagnosis

Early findings, especially if rash is present, may suggest enterovirus, measles, or rubella infection. Enteric fever may be an early consideration because of the presence of leukopenia and thrombocytopenia. A history of tick bite, which is often obtained; information about local risk; and the biphasic fever pattern will help with the diagnosis. Because of the wilderness exposure, diseases such as leptospirosis, borreliosis, tularemia, ehrlichiosis, and Rocky Mountain spotted fever will be considerations.

Complications

Meningoencephalitis occurs in 3%–7% of patients. Cardiac and pulmonary complications are rare.

Prevention & Treatment

Prevention involves avoiding endemic areas and using conventional means to avoid tick bite. Therapy is supportive. Do not use analgesics that modify platelet function.

OTHER MAJOR VIRAL CHILDHOOD EXANTHEMS

See the earlier section on Infections due to Herpesviruses for a discussion of varicella and roseola, the two other major childhood exanthems.

ERYTHEMA INFECTIOSUM

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fever and rash with “slapped-cheek” appearance, followed by a symmetrical, full-body maculopapular rash.
- Arthritis in older children.
- Profound anemia in patients with impaired erythrocyte production.
- Nonimmune hydrops fetalis following infection of pregnant women.

General Considerations

This benign exanthematous illness of school-aged children is caused by the human parvovirus designated B19. Spread is respiratory, occurring in winter–spring epidemics. A nonspecific mild flulike illness may occur during the viremia at 7–10 days; the characteristic rash occurring at 10–17 days represents an immune response. The patient is viremic and contagious prior to—but not after—the onset of rash.

Approximately half of infected individuals have a subclinical illness. Most cases (60%) occur in children between ages 5 and 15 years, with an additional 40% occurring later in life. Forty percent of adults are seronegative. The disease is moderately contagious; the secondary attack rate in a school or household setting is 50% among susceptible children and 20%–30% among susceptible adults.
Clinical Findings

Owing to the nonspecific nature of the exanthem and the many subclinical cases, a history of contact with an infected individual is often absent or unreliable. Recognition of the illness is easier during outbreaks.

A. Symptoms and Signs

Typically, the first sign of illness is the rash, which begins as raised, fiery red maculopapular lesions on the cheeks that coalesce to give a “slapped-cheek” appearance. The lesions are warm, nontender, and sometimes pruritic. They may be scattered on the forehead, chin, and postauricular areas, but the circumoral region is spared. Within 1–2 days, similar lesions appear on the proximal extensor surfaces of the extremities and spread distally in a symmetrical fashion. Palms and soles are usually spared. The trunk, neck, and buttocks are also commonly involved. Central clearing of confluent lesions produces a characteristic lacelike pattern. The rash fades in several days to several weeks but frequently reappears in response to local irritation, heat (bathing), sunlight, and stress. Nearly 50% of infected children have some rash remaining (or recurring) for 10 days. Fine desquamation may be present. Mild systemic symptoms occur in up to 50% of children. These symptoms include low-grade fever, mild malaise, sore throat, and coryza. These symptoms appear for 2–3 days followed by a week-long asymptomatic phase before the rashes appear.

Purpuric stocking-glove rashes, neurologic disease, and severe disorders resembling hemolytic-uremic syndrome have also been described in association with parvovirus B19.

B. Laboratory Findings

A mild leukopenia occurs early in some patients, followed by leukocytosis and lymphocytosis. Specific IgM and IgG serum antibody tests are available, but care must be used in choosing a reliable laboratory for this test. IgM antibody is present in 90% of patients at the time of the rash. Nucleic acid detection tests are often definitive, but parvovirus DNA may be detectable in blood for as long as 9 months after infection. The disease is not diagnosed by routine viral culture.

Differential Diagnosis

In children immunized against measles and rubella, parvovirus B19 is the most frequent agent of morbilliform and rubelliform rashes. The characteristic rash and the mild nature of the illness distinguish erythema infectiousum from other childhood exanthems. It lacks the prodromal symptoms of measles and the lymphadenopathy of rubella. Systemic symptoms and pharyngitis are more prominent with enteroviral infections and scarlet fever.

Complications & Sequelae

A. Arthritis

Arthritis is more common in older patients, beginning with late adolescence. Approximately 10% of older children have severe joint symptoms. Girls are affected more commonly than boys. Pain and stiffness occur symmetrically in the peripheral joints. Arthritis usually follows the rash and may persist for 2–6 weeks but resolves without permanent damage.

B. Aplastic Crisis and Other Hematologic Abnormalities

Parvovirus B19 replicates primarily in erythroid progenitor cells. Consequently, reticulocytopenia occurs for approximately 1 week during the illness. This goes unnoticed in individuals with a normal erythrocyte half-life, but results in severe anemia in patients with chronic hemolytic anemia.

Pure red cell aplasia, leukopenia, pancytopenia, idiopathic thrombocytopenic purpura, and a hemophagocytic syndrome have been described. Patients with HIV infection and other immunosuppressive illnesses may develop prolonged anemia or pancytopenia. Patients with hemolytic anemia and aplastic crisis, or with immunosuppression, may be contagious and should be isolated while in the hospital.

C. Other End-Organ Infections

Parvovirus is under study as a potential cause of a variety of collagen-vascular diseases. Parvovirus has been associated with neurologic syndromes, hepatitis, and suppression of bone marrow lineages. It is implicated as a cause of myocarditis.

D. In Utero Infections

Infection of susceptible pregnant women may produce fetal infection with hydrops fetalis. Fetal death occurs in about 6% of cases; most fatalities occur in the first 20 weeks. This is higher than the rate of fetal loss expected in typical pregnancies. Congenital anomalies have not been associated with parvovirus B19 infection during pregnancy.

Treatment & Prognosis

Erythema infectiousum is a benign illness for immunocompetent individuals. Patients with aplastic crisis may require blood transfusions. It is unlikely that this complication can be prevented by quarantine measures, because acute parvovirus infection in contacts is often unrecognized and is most contagious prior to the rash. Pregnant women who are exposed to erythema infectiousum or who work in a setting in which an epidemic occurs should be tested for evidence of prior infection. Susceptible pregnant women should then be followed up for evidence of parvovirus infection.
Approximately 1.5% of women of childbearing age are infected during pregnancy. If maternal infection occurs, the fetus should be followed by ultrasonography for evidence of hydrops and distress. In utero transfusion or early delivery may salvage some fetuses. Pregnancies should not be terminated because of parvovirus infection. The risk of fetal death among exposed pregnant women of unknown serologic status is less than 2.5% for homemakers and less than 1.5% for school teachers.

Intramuscular immune globulin is not protective. High-dose IVIG has stopped viremia and led to marrow recovery in some cases of prolonged aplasia. Its role in immunocompetent patients and pregnant women is unknown.

MEASLES (RUBEOLA)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Exposure to measles 9–14 days previously.
- Prodrome of fever, cough, conjunctivitis, and coryza.
- Koplik spots (few to many small white papules on a diffusely red base on the buccal mucosa) 1–2 days prior to and after onset of rash.
- Maculopapular rash spreading down from the face and hairline to the trunk over 3 days and later becoming confluent.
- Leukopenia.

Clinical Findings

A history of contact with a suspected case may be absent because airborne spread is efficient and patients are contagious during the prodrome. Contact with an imported case may not be recognized. In temperate climates, epidemic measles is a winter–spring disease. Because measles is uncommon in the United States, many suspected cases are misdiagnoses of other viral infections.

A. Symptoms and Signs

High fever and lethargy are prominent. Sneezing, eyelid edema, tearing, copious coryza, photophobia, and harsh cough ensue and worsen. Koplik spots are white macular lesions on the buccal mucosa, typically opposite the lower molars. These are almost pathognomonic for rubeola, although they may be absent. A discrete maculopapular rash begins when the respiratory symptoms are maximal and spreads quickly over the face and trunk, coalescing to a bright red. As it spreads to the extremities, the rash fades from the face and is completely gone within 6 days; fine desquamation may occur. Fever peaks when the rash appears and usually falls 2–3 days thereafter.

B. Laboratory Findings

Lymphopenia is characteristic. Total leukocyte counts may fall to 1500/µL. The diagnosis is usually made by detection of measles IgM antibody in serum drawn at least 3 days after the onset of rash; diagnosis may be made later by detection of a significant rise in IgG antibody. Direct detection of measles antigen by fluorescent antibody staining of nasopharyngeal cells is a useful rapid method. PCR testing of oropharyngeal secretions or urine is extremely sensitive, specific, and can detect infection up to 5 days before symptoms.

C. Imaging

Chest radiographs often show hyperinflation, perihilar infiltrates, or parenchymal patchy, fluffy densities. Secondary consolidation or effusion may be visible.

Differential Diagnosis

Table 40–3 lists other illnesses that may resemble measles.

Complications & Sequelae

A. Respiratory Complications

These complications occur in up to 15% of patients. Bacterial superinfection of the lungs, middle ear, sinus, and cervical
nodes are most common. Fever that persists after the third or fourth day of rash suggests such a complication, as does leukocytosis. Bronchospasm, severe croup, and progressive viral pneumonia or bronchiolitis (in infants) also occur. Immunosuppressed patients are at much greater risk for fatal pneumonia than are immunocompetent patients.

B. Cerebral Complications

Encephalitis occurs in 1 in 2000 cases. Onset is usually within a week after appearance of rash. Symptoms include combativeness, ataxia, vomiting, seizures, and coma. Lymphocytic pleocytosis and a mildly elevated protein concentration are usual CSF findings, but the fluid may be normal. Forty percent of patients so affected die or have severe neurologic sequelae.

Subacute sclerosing panencephalitis (SSPE) is a slow measles virus infection of the brain that becomes symptomatic years later in about 1 in 100,000 previously infected children. This progressive cerebral deterioration is associated with myoclonic jerks and a typical electroencephalographic pattern. It is fatal in 6–12 months. High titers of measles antibody are present in serum and CSF.

C. Other Complications

These include hemorrhagic measles (severe disease with multorgan bleeding, fever, cerebral symptoms), thrombocytopenia, appendicitis, keratitis, myocarditis, and premature delivery or stillbirth. Mild liver function test elevation is detected in up to 50% of cases in young adults; jaundice may also occur. Measles causes transient immunosuppression; thus, reactivation or progression of tuberculosis (including transient cutaneous anergy) can occur in children with untreated tuberculosis.

Prevention

The current two-dose active vaccination strategy is successful. Vaccine should not be withheld for concurrent mild acute illness, tuberculosis or positive tuberculin skin test, breast feeding, or exposure to an immunodeficient contact. The vaccine is recommended for HIV-infected children without severe HIV complications and adequate CD4 cells (≥ 15%).

Treatment & Prognosis

Vaccination prevents the disease in susceptible exposed individuals if given within 72 hours (see Chapter 10). Immune globulin (0.25 mL/kg intramuscularly; 0.5 mL/kg if immunocompromised) will prevent or modify measles if given within 6 days. Suspected cases should be diagnosed promptly and reported to the local health department.

Recovery generally occurs 7–10 days after onset of symptoms. Therapy is supportive: eye care, cough relief (avoid opioid suppressants in infants), and fever reduction (acetaminophen, lukewarm baths; avoid salicylates). Secondary bacterial infections should be treated promptly; antimicrobial prophylaxis is not indicated. Ribavirin is active in vitro and may be useful in infected immunocompromised children. In malnourished children, vitamin A supplementation should be given to attenuate the illness.

RUBELLA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- History of rubella vaccination usually absent.
- Prodromal nonspecific respiratory symptoms and adenopathy (postauricular and occipital).
- Maculopapular rash beginning on face, rapidly spreading to the entire body, and disappearing by fourth day.
- Few systemic symptoms.
- Congenital infection.
  - Retarded growth, development.
  - Cataracts, retinopathy.
  - Purpuric “blueberry muffin” rash at birth.
  - Jaundice, thrombocytopenia.
  - Deafness.
  - Congenital heart defect.

General Considerations

If it were not teratogenic, rubella would be of little clinical importance. Clinical diagnosis is difficult in some cases because of its variable expression. In one study, over 80% of infections were subclinical. Rubella is transmitted by aerosolized respiratory secretions. Patients are infectious 5 days before until 5 days after the rash. Endemic rubella is absent in the United States and the Americas, and congenital rubella in infants born to unimmunized women and the occasional woman who is reinfected in pregnancy, is now very rare. Sporadic cases occur in migrants to the United States.
Clinical Findings

The incubation period is 14–21 days. The nondistinctive signs may make exposure history unreliable. A history of immunization makes rubella unlikely but still possible. Congenital rubella usually follows maternal infection in the first trimester.

A. Symptoms and Signs

1. Infection in children—Young children may only have rash. Older patients often have a nonspecific prodrome of low-grade fever, ocular pain, sore throat, and myalgia. Postauricular and suboccipital adenopathy (sometimes generalized) is characteristic. This often precedes the rash or may occur without rash. The rash consists of erythematous discrete maculopapules beginning on the face. A “slapped-cheek” appearance or pruritus may occur. Scarletiform or morbilliform rash variants may occur. The rash spreads quickly to the trunk and extremities after fading from the face; it is gone by the fourth day. Enanthema is usually absent.

2. Congenital infection—More than 80% of women infected in the first 4 months of pregnancy (25% near the end of the second trimester) deliver an affected infant; congenital disease occurs in less than 5% of women infected later in pregnancy. Later infections can result in isolated defects, such as deafness. The main manifestations are as follows:

a. Growth retardation—Between 50% and 85% of infants are small at birth and remain so.

b. Cardiac anomalies—Pulmonary artery stenosis, patent ductus arteriosus, ventricular septal defect.

c. Ocular anomalies—Cataracts, microphthalmia, glaucoma, retinitis.

d. Deafness—Sensorineural (> 50% of cases).

e. Cerebral disorders—Chronic encephalitis; retardation.

f. Hematologic disorders—Thrombocytopenia, dermal nests of extramedullary hematopoiesis or purpura (“blueberry muffin” rash), lymphopenia.

g. Others—Hepatitis, osteomyelitis, immune disorders, malabsorption, diabetes.

B. Laboratory Findings

Leukopenia is common, and platelet counts may be low. Congenital infection is associated with low platelet counts, abnormal liver function tests, hemolytic anemia, and CSF pleocytosis. Total serum IgM is elevated, and IgA and IgG levels may be depressed.

C. Imaging

Pneumonitis and bone metaphyseal longitudinal lucencies may be present in radiographs of children with congenital infection.

C. Imaging

Pneumonitis and bone metaphyseal longitudinal lucencies may be present in radiographs of children with congenital infection.

Differential Diagnosis

Rubella may resemble infections due to enterovirus, adenovirus, measles, EBV, roseola, parvovirus, and T. gondii. Drug reactions may also mimic rubella. Because public health implications are great, sporadic suspected cases should be confirmed serologically or virologically.

C. Rubella in Pregnancy

Infection in the mother is self-limited and not severe.

Complications & Sequelae

A. Arthralgia and Arthritis

Both occur more often in adult women. Polyarticular involvement (fingers, knees, wrists), lasting a few days to weeks, is typical. Frank arthritis occurs in a small percentage of patients. It may resemble acute rheumatoid arthritis.

B. Encephalitis

With an incidence of about 1:6000, this is a nonspecific paramyxovirus associated with a low mortality rate. A syndrome resembling SSPE (see section on Measles) has also been described in congenital rubella.

C. Rubella in Pregnancy

Infection in the mother is self-limited and not severe.

Prevention

Rubella is one of the infections that could be eradicated (see Chapter 10 for the indication and efficacy of rubella vaccine). Standard prenatal care should include rubella antibody testing. Seropositive mothers are at no risk; seronegative mothers are vaccinated after delivery.
A pregnant woman possibly exposed to rubella should be tested immediately; if seropositive, she is immune and need not worry. If she is seronegative, a second specimen should be drawn in 4 weeks, and both specimens should be tested simultaneously. Seroconversion in the first trimester is associated with high fetal risk; such women require counseling regarding therapeutic abortion.

When pregnancy termination is not an option, some experts recommend intramuscular administration of immune globulin (up to 0.55 mL/Kg IM) within 72 hours after exposure in an attempt to prevent infection. (This negates the value of subsequent antibody testing.) The efficacy of this practice is unknown.

Treatment & Prognosis

Symptomatic therapy is sufficient. Arthritis may improve with administration of anti-inflammatory agents. The prognosis is poor in congenitally infected infants, in whom most defects are irreversible or progressive. The severe cognitive defects in these infants seem to correlate closely with the degree of growth failure.

INFECTIONS DUE TO OTHER VIRUSES

HANTAVIRUS CARDIOPULMONARY SYNDROME

Essentials of Diagnosis & Typical Features

- Influenza-like prodrome (fever, myalgia, headache, cough).
- Rapid onset of unexplained pulmonary edema and myocardopathy.
- Residence or travel in endemic area; exposure to aerosols from deer mouse droppings or secretions.

General Considerations

Hantavirus cardiopulmonary syndrome is the first native bunyavirus infection endemic in the United States. This syndrome is distinctly different in mode of spread (no arthropod vector) and clinical picture from other bunyavirus diseases.

Clinical Findings

The initial cases of hantavirus cardiopulmonary syndrome involved travel to or residence in a limited area in the southwestern United States where there was a potential for exposure to the reservoir, the deer mouse. Since this and many other related rodents live in many other locales, the disease has been confirmed in more than 30 states and Canada. Epidemics occur when environmental conditions favor large increases in the rodent population and increased prevalence of virus in this reservoir.

A. Symptoms and Signs

After an incubation period of 1–3 weeks, onset is sudden, with a nonspecific virus-like prodrome: fever; back, hip, and leg pain; chills; headache; and nausea and vomiting. Abdominal pain may be present. Sore throat, conjunctivitis, rash, and adenopathy are absent, and respiratory symptoms are absent or limited to a dry cough. After 1–10 days (usually 3–7), dyspnea, tachypnea, and evidence of a pulmonary capillary leak syndrome appear. This often progresses rapidly over hours. Hypotension is common, not only from hypoxemia but also from myocardial dysfunction. Copious, amber-colored, nonpurulent secretions are common. Decreased cardiac output due to myocardiopathy and elevated systemic vascular resistance distinguish this disease from early bacterial sepsis.

B. Laboratory Findings

The hemogram shows leukocytosis with a prominent left shift and immunoblasts, thrombocytopenia, and hemococoncentration. Lactate dehydrogenase (LDH) is elevated, as are liver function tests; serum albumin is low. Creatinine is elevated in some patients, and proteinuria is common. Lactic acidosis and low venous bicarbonate are poor prognostic signs. A serum IgM ELISA test is positive early in the illness. Otherwise, the diagnosis is made by specific staining of tissue or PCR, usually at autopsy.

C. Imaging

Initial chest radiographs are normal. Subsequent radiographs show bilateral interstitial infiltrates with the typical butterfly pattern of acute pulmonary edema, bibasilar airspace disease, or both. Significant pleural effusions are often present. These findings contrast with those of other causes of acute respiratory distress syndrome.

Differential Diagnosis

In some geographic areas, plague and tularemia may be possibilities. Infections with viral respiratory pathogens and *Mycoplasma* have a slower tempo, do not elevate the LDH, and do not cause the hematologic changes seen in this
syndrome. Q fever, psittacosis, toxin exposure, legionellosis, and fungal infections are possibilities, but the history, tempo of the illness, and blood findings, as well as the exposure history, should be distinguishing features. Hantavirus cardiopulmonary syndrome is a consideration in previously healthy persons with a febrile illness associated with unexplained pulmonary edema.

**Treatment & Prognosis**

Ribavirin, to which hantaviruses and other bunyaviruses are susceptible, has not been demonstrated to alter the course of the illness. Management should concentrate on oxygen therapy and mechanical ventilation as required. Because of capillary leakage, Swan-Ganz catheterization to monitor cardiac output and inotropic support—rather than fluid therapy—should be used to maintain perfusion. Venoarterial extracorporeal membrane oxygenation can provide short-term support for selected patients. The strains of virus present in North America are not spread by person-to-person contact. No isolation is required. The case fatality rate is 30%–40%. Guidelines are available for reduction of exposure to the infectious agent.

**MUMPS**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- No prior mumps immunization.
- Parotid gland swelling.
- Aseptic meningitis with or without parotitis.

**General Considerations**

Mumps was one of the classic childhood infections; virus spread by the respiratory route attacked almost all unimmunized children (asymptomatically in 30%–40% of cases), and produced lifelong immunity. The vaccine is so efficacious that clinical disease is rare in immunized children. As a result of subclinical infections or childhood immunization, 95% of adults are immune, although immunity can wane in late adolescence. When susceptibles accumulate occasional epidemics (~400 cases in 2012) can occur, which are aborted by reimmunization of the at-risk population. Infected patients can spread the infection from 1 to 2 days prior to the onset of symptoms and for 5 additional days. The incubation period is 14–21 days.

A history of exposure to a child with parotitis is not proof of mumps exposure. In an adequately immunized individual, parotitis is usually due to another cause. Currently in the United States, less than one case is reported per 100,000 population.

**Clinical Findings**

**A. Symptoms and Signs**

1. **Salivary gland disease**—Tender swelling of one or more glands, variable fever, and facial lymphedema are typical. Parotid involvement is most common; this is bilateral in 70% of patients. The ear is displaced upward and outward; the mandibular angle is obliterated. Systemic toxicity is usually absent. Parotid stimulation with sour foods may be quite painful. The orifice of the Stensen duct may be red and swollen; yellow secretions may be expressed, but pus is absent. Parotid swelling dissipates after 1 week.

2. **Meningoencephalitis**—Prior to widespread immunization, mumps was the most common cause of aseptic meningitis, which is usually manifested by mild headache or asymptomatic mononuclear pleocytosis. Fewer than 10% of patients have clinical meningitis or encephalitis. Cerebral symptoms do not correlate with parotid symptoms, which are absent in many patients with meningoencephalitis. Although neck stiffness, nausea, and vomiting can occur, encephalitic symptoms are rare (1:4000 cases of mumps); recovery in 3–10 days is the rule.

3. **Pancreatitis**—Abdominal pain may represent transient pancreatitis. Because salivary gland disease may elevate serum amylase, specific markers of pancreatic function (lipase, amylase isoenzymes) are required for assessing pancreatic involvement.

4. **Orchitis, oophoritis**—Involvement of the gonads is associated with fever, local tenderness, and swelling. Epididymitis is usually present. Orchitis is unusual in young children, but occurs in up to one-third of affected postpubertal males. Usually, it is unilateral and resolves in 1–2 weeks. Although one-third of infected testes atrophy, bilateral involvement and sterility are rare.

5. **Other**—Thyroiditis, mastitis (especially in adolescent females), arthritis, and presternal edema (occasionally with dysphagia or hoarseness) may be seen.

**B. Laboratory Findings**

Peripheral blood leukocyte count is usually normal. Up to 1000 cells/μL (predominantly lymphocytes) may be present.
in the CSF, with mildly elevated protein and normal to slightly decreased glucose. Viral culture or PCR tests of saliva, throat, urine, or spinal fluid may be positive for at least 1 week after onset. Paired sera assayed by ELISA or a single positive IgM antibody test are currently used for diagnosis.

**Differential Diagnosis**

Mumps parotitis may resemble the following conditions: cervical adenitis (the jaw angle may be obliterated, but the ear does not usually protrude; the Stensen duct orifice is normal; leukocytosis and neutrophilia are observed), bacterial parotitis (pus in the Stensen duct, toxicity, exquisite tenderness), recurrent parotitis (idiopathic or associated with calculi), tumors or leukemia, and tooth infections. Many viruses, including parainfluenza, enteroviruses, EBV, CMV, and influenza virus, can cause parotitis. Parotid swelling in HIV infection is less painful and tends to be bilateral and chronic, but bacterial parotitis occurs in some children with HIV infection.

Unless parotitis is present, mumps meningitis resembles that caused by enteroviruses or early bacterial infection. An elevated amylase level is a useful clue in this situation. Isolated pancreatitis is not distinguishable from many other causes of epigastric pain and vomiting. Mumps is a classic cause of orchitis, but torsion, bacterial or chlamydial epididymitis, *Mycoplasma* infection, other viral infections, hematomas, hernias, and tumors must also be considered.

**Complications**

The major neurologic complication is nerve deafness (usually unilateral) which can result in inability to hear high tones. It may occur without meningitis. Permanent damage is rare, occurring in less than 0.1% of cases of mumps. Aqueductal stenosis and hydrocephalus (especially following congenital infection), myocarditis, transverse myelitis, and facial paralysis are other rare complications.

**Treatment & Prognosis**

Treatment is supportive and includes provision of fluids, analgesics, and scrotal support for orchitis. Systemic corticosteroids have been used for orchitis, but their value is anecdotal.

---

RABIES

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- History of animal bite 10 days to 1 year (usually < 90 days) previously.
- Paresthesias or hyperesthesia in bite area.
- Progressive limb and facial weakness in some patients (dumb rabies; 30%).
- Irritability followed by fever, confusion, combativeness, muscle spasms (especially pharyngeal with swallowing) in all patients (furious rabies).
- Rabies antigen detected in corneal scrapings or tissue obtained by brain or skin biopsy; Negri bodies seen in brain tissue.

**General Considerations**

Rabies remains a potentially serious public health problem wherever animal immunization is not widely practiced or when humans play or work in areas with sylvan rabies. Although infection does not always follow a bite by a rabid animal (about 40% infection rate), infection is almost invariably fatal. Any warm-blooded animal may be infected, but susceptibility and transmissibility vary with different species. Bats often carry and excrete the virus in saliva or feces for prolonged periods; they are the major cause of rabies in the United States. Dogs and cats are usually clinically ill within 10 days after becoming contagious (the standard quarantine period for suspect animals). Valid quarantine periods or signs of illness are not fully known for many species. Rodents rarely transmit infection. Animal vaccines are very effective when properly administered, but a single inoculation may fail to produce immunity in up to 20% of dogs.

The risk is assessed according to the type of animal (bats are always considered to have a high likelihood of being rabid; raccoons, skunks, foxes in many areas), wound extent and location (infection more common after head or hand bites, or if wounds have extensive salivary contamination and are not quickly and thoroughly cleaned), geographic area (urban rabies is rare to nonexistent in the U.S. cities; rural rabies is possible, especially outside the United States), and animal vaccination history (risk low if documented).

Most rabies in the United States is caused by genotypes found in bats, yet a history of bat bite is often not obtained. Aerosolized virus in caves inhabited by bats has caused infection.

---

**Clinical Findings**

**A. Symptoms and Signs**

Paresthesias at the bite site is usually the first symptom. Nonspecific anxiety, excitability, or depression follows, then muscle spasms, drooling, hydrophobia, delirium, and lethargy. Swallowing or even the sensation of air blown on the face may cause pharyngeal spasms. Seizures, fever, cranial nerve palsies, coma, and death follow within 7–14 days after onset. In a minority of patients, the spastic components are initially absent and the symptoms are primarily flaccid paralysis and cranial nerve defects. The furious components appear subsequently.

**B. Laboratory Findings**

Leukocytosis is common. CSF is usually normal, but may show elevation of protein and mononuclear cell pleocytosis. Cerebral imaging and electroencephalography are not diagnostic.

Infection in an animal may be determined by use of the fluorescent antibody test to examine brain tissue for antigen. Rabies virus is excreted in the saliva of infected humans, but the diagnosis is usually made by antigen detection in scrapings or tissue samples of richly innervated epithelium, such as the cornea or the hairline of the neck. Classic Negri cytoplasmic inclusion bodies in brain tissue are not always present. Serocconversion occurs after 7–10 days.

**Differential Diagnosis**

Failure to elicit the bite history in areas where rabies is rare may delay diagnosis. Other disorders to be considered include parainfectious encephalopathy; encephalitis due to herpes simplex, mosquito-borne viruses, or other causes of viral encephalitis; and Guillain-Barré syndrome. However, classic furious rabies is not readily confused with these alternative diagnoses.

**Prevention**

See Chapter 10 for information regarding vaccination and postexposure prophylaxis. Rabies immune globulin and diploid cell vaccine have made prophylaxis more effective and minimally toxic. Because rabies is almost always fatal, presumed exposures must be managed carefully.

**Treatment & Prognosis**

Survival is very rare, but has been reported in patients receiving meticulous intensive care and a variety of antiviral therapies of unproven benefit. Early diagnosis is important for the protection and prophylaxis of individuals exposed to the patient.

---

**Rickettsial Infections**

Rickettsiae are pleomorphic, gram-negative coccobacilli that are obligate intracellular parasites. Rickettsial diseases are often included in the differential diagnosis of febrile rashes. Severe headache, myalgia, and pulmonary symptoms are prominent manifestations of rickettsial disease. The endothelium is the primary target tissue, and the ensuing vasculitis is responsible for severe illness.

All rickettsioses are transmitted by cutaneous arthropod contact (ticks, fleas, mice, lice—depending on the disease), either by bite or by contamination of skin breaks with vector feces. In all except Rocky Mountain spotted fever and murine typhus, there is a characteristic eschar at the bite site, called the tache noire. Evidence of such contact by history or physical examination may be completely lacking, especially in young children. The geographic distribution of the vector is often the primary determinant for suspicion of these infections. Therapy often must be empiric. Many new broad-spectrum antimicrobials are inactive against these cell wall–deficient organisms; tetracycline is usually effective.

Q fever, which is not rickettsiae, is included here because it was long classified as such and, like rickettsiae, is an obligate intracellular bacterium. It is not transmitted by an insect vector and is not characterized by rash.

**Human Ehrlichiosis**

**Essentials of Diagnosis & Typical Features**

- Residing or travel in endemic area when ticks are active.
- Tick bite noted (~75%).
- Fever, headache, rash (~67%), gastrointestinal symptoms.
- Leukopenia, thrombocytopenia, elevated serum transaminases, hypoalbuminemia.
- Definitive diagnosis by specific serology.

In children, the major agent of North American human ehrlichiosis is *Ehrlichia chaffeensis*. The reservoir hosts are probably wild rodents, deer, and sheep; ticks are the vectors. Most cases caused by this agent are reported in the south-central, southeastern, and middle Atlantic states. Arkansas, Missouri, Oklahoma, Kentucky, Tennessee, and North Carolina are high-prevalence areas. Almost all cases occur between March and October, when ticks are active.

A second ehrlichiosis syndrome, seen in the upper Midwest and Northeast (Connecticut, Wisconsin, Minnesota, and New York are high-prevalence areas), is...
caused by *Anaplasma phagocytophilum* and *Ehrlichia ewingii*. Anaplasmosis also occurs in the western United States. New pathogenic *Ehrlichia* species have been discovered recently. *E. chaffeensis* has a predilection for mononuclear cells, whereas *A. phagocytophilum* and *E. ewingii* infect and produce intracytoplasmic inclusions in granulocytes. Hence, diseases caused by these agents are referred to as human monocytic ehrlichiosis or human granulocytic ehrlichiosis, respectively. Ehrlichiosis, Lyme disease, and babesiosis share some tick vectors; thus, dual infections are common and should be considered in patients who fail to respond to therapy.

**Clinical Findings**

In approximately 75% of patients, a history of tick bite can be elicited. The majority of the remaining patients report having been in a tick-infested area. The usual incubation period is 5–21 days.

**A. Symptoms and Signs**

Fever is universally present and headache is common (less so in children). Gastrointestinal symptoms (abdominal pain, anorexia, nausea, and vomiting) are reported in most pediatric patients. Distal limb edema may occur. Chills, photophobia, conjunctivitis, and myalgia occur in more than half of patients. Rash occurs in two-thirds of children with monocytic ehrlichiosis, but is less common (~50%) in granulocytic ehrlichiosis. Rash may be erythematous, macular, papular, petechial, scarlatiniform, or vasculitic. Meningitis occurs. Interstitial pneumonitis, acute respiratory distress syndrome, and renal failure occur in severe cases. Physical examination reveals rash (not usually palms and soles), mild adenopathy, and hepatomegaly. In children without a rash, infection may present as a fever of unknown origin.

**B. Laboratory Findings**

Laboratory abnormalities include leukopenia with left shift, lymphopenia, thrombocytopenia, and elevated aminotransferase levels. Hypoalbuminemia and hyponatremia are common. Disseminated intravascular coagulation can occur in severe cases. Anemia occurs in one-third of patients. CSF pleocytosis (mononuclear cells; increased protein) is common. The definitive diagnosis is made serologically, either by a single high titer or a fourfold rise in titer. The Centers for Disease Control and Prevention uses appropriate antigens in an immunofluorescent antibody test in order to distinguish between the etiologic agents. Intracytoplasmic inclusions (morulae) may occasionally be observed in mononuclear cells in monocytic ehrlichiosis, and are usually observed in polymorphonuclear cells from the peripheral blood or bone marrow in granulocytic ehrlichiosis. Specific PCR testing can provide an early diagnosis where this is available.

**Differential Diagnosis**

In regions where these infections exist, ehrlichiosis should be included in the differential diagnosis of children who present during tick season with fever, leukopenia or thrombocytopenia (or both), increased serum transaminase levels and rash. The differential diagnosis includes septic or toxic shock, other rickettsial infections (especially Rocky Mountain spotted fever), Colorado tick fever, leptospirosis, Lyme borreliosis, relapsing fever, EBV, CMV, viral hepatitis and other viral infections, Kawasaki disease, systemic lupus erythematosus, and leukemia.

**Treatment & Prognosis**

Asymptomatic or clinically mild and undiagnosed infections are common in some endemic areas. The disease may last several weeks if untreated. One-quarter of hospitalized children require intensive care. Meningoencephalitis and persisting neurologic deficits occur in 5%–10% of patients. Doxycycline, 2 mg/kg every 12 hours (IV or PO; maximum 100 mg per dose) for 7–10 days, is the treatment of choice. Patients with suspected disease must be treated preemptively concurrently with attempts to establish the diagnosis. Response to therapy should be evident in 24–48 hours. Deaths are uncommon in children but do occur. Immune compromise and asplenia are risk factors for severe disease.

**ROCKY MOUNTAIN SPOTTED FEVER**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Residing or travel in endemic area when ticks are active.
- Fever, rash (palms and soles), gastrointestinal symptoms, headache.
- Tick bite (50%).
- Thrombocytopenia, hyponatremia.
- Definitive diagnosis by specific serology.

*Rickettsia rickettsii* causes one of many similar tick-borne illnesses characterized by fever and rash that occur worldwide. Most are named after their geographic area. Dogs...
and rodents, as well as large mammals, are reservoirs of *R. rickettsii*.

Rocky Mountain spotted fever is the most severe rickettsial infection and the most important (~1000 cases per year) in the United States. It occurs predominantly along the eastern seaboard; in the southeastern states; and in Arkansas, Texas, Missouri, Kansas, and Oklahoma. It is much less common in the west. Most cases occur in children exposed in rural areas from April to September. Because tick attachment lasting 6 hours or longer is needed, frequent tick removal is a preventive measure. Infection can be acquired from dog ticks.

**Clinical Findings**

**A. Symptoms and Signs**

After the incubation period of 3–12 days (mean, 7 days), there is high fever (> 40°C, often hectic), usually of abrupt onset, myalgia, severe and persistent headache (retro-orbital), toxicity, photophobia, vomiting, abdominal pain, and diarrhea. A rash occurs in more than 95% of patients and appears 2–6 days after fever onset as macules and papules; most characteristic (65%) is involvement of the palms, soles, and extremities. The rash becomes petechial and spreads centrally from the extremities. The rash reflects infection of endothelial cells, which also causes vascular leak and resulting edema, hypovolemia, and hypotension. Conjunctivitis, splenomegaly, pneumonia, meningismus, and confusion may occur.

**B. Laboratory Findings**

Laboratory findings are nonspecific and reflect diffuse vasculitis: thrombocytopenia, hyponatremia, early mild leukopenia, proteinuria, mildly abnormal liver function tests, hypoalbuminemia, and hematuria. CSF pleocytosis is common. Serologic diagnosis is achieved with indirect fluorescent or latex agglutination antibody methods, but generally is informative only 7–10 days after onset of the illness. Skin biopsy with specific fluorescent staining is a specific and moderately sensitive diagnostic method available during the first week of the illness.

**Differential Diagnosis**

The differential diagnosis includes meningococcemia, measles, meningococcal meningitis, staphylococcal sepsis, enteroviral infection, leptospirosis, Colorado tick fever, scarlet fever, murine typhus, Kawasaki disease, and ehrlichiosis.

**Treatment & Prognosis**

To be effective, therapy for Rocky Mountain spotted fever must be started early, most often on the basis of a high clinical suspicion prior to rash onset in endemic areas. It is important to remember that atypical presentations, such as the absence of pathognomonic rash, often lead to delay in appropriate therapy. Rash is rarely present during the first day of diagnosis and in 50% within 3 days of onset of fever. Doxycycline is the treatment of choice for children, regardless of age. Dosing is 2 mg/kg every 12 hours (IV or PO; maximum 100 mg per dose) for 2 or 3 days after the temperature has returned to normal for a full day. A minimum of 10 days of therapy is recommended.

Complications and death result from severe vasculitis, especially in the brain, heart, and lungs. The mortality rate is 5%–7%. Persistent neurologic deficits occur in 10%–15% of children who recover. Delay in therapy is an important determinant of sequelae and mortality.

**ENDEMIC TYPHUS (MURINE TYPHUS)**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Residing in endemic area.
- Fever for 10–14 days.
- Headache, chills, myalgia.
- Maculopapular rash spreading from trunk to extremities (not on palms and soles) 3–7 days after fever onset.
- Definitive diagnosis by serology.

Endemic typhus is present in the southern United States, mainly in southern Texas, and in Southern California, and in Hawaii. The disease is transmitted by fleas from infected rodents or by inhalation. Domestic cats, dogs, and opossums may play a role in the transmission of suburban cases. No eschar appears at the inoculation site, which may go unnoticed. The incubation period is 6–14 days. Headache, myalgia and arthralgia, and chills slowly worsen. Fever may last 10–14 days. After 3–7 days, a rash appears. Truncal macules and papules spread to the extremities; the rash is rarely petechial. The rash resolves in less than 5 days. The location of the rash in typhus, with sparing of the palms and soles, helps distinguish the disease from Rocky Mountain spotted fever. Rash may be absent in 20%–40% of patients. Hepatomegaly may be present. Intestinal and respiratory symptoms may occur. Mild thrombocytopenia and elevated liver enzymes may be present. The illness is usually self-limited and milder than epidemic typhus. More prolonged neurologic
symptoms have been described. Clinicians in endemic areas should consider early treatment when presented with a child with protracted fever, rash, and headache. Doxycycline is the drug of choice, which should be continued for 3 days after evidence of clinical improvement. Fluorescent antibody and ELISA tests are available.

Q FEVER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Exposure to farm animals (sheep, goats, cattle) and pets.
- Flulike illness (fever, severe headache, myalgia).
- Cough; atypical pneumonia.
- Hepatomegaly and hepatitis.
- Diagnosis by serology.

Coxiella burnetii is transmitted by inhalation rather than by an arthropod bite. Q fever is also distinguished from rickettsial diseases by the infrequent occurrence of cutaneous manifestations and by the prominence of pulmonary disease. The birth tissues and excreta of domestic animals and of some rodents are major infectious sources. The organisms may be carried long distances in fine particle aerosols. Unpasteurized milk from infected animals may also transmit disease.

Clinical Findings

A. Symptoms and Signs

Most patients have a self-limited flulike syndrome of chills, fever, severe headache, and myalgia of abrupt onset occurring 10–25 days after exposure. Abdominal pain, vomiting, chest pain, and dry cough are prominent in children. Examination of the chest may produce few findings, as in other atypical pneumonias. Hepatosplenomegaly is common. The illness lasts 1–4 weeks and frequently is associated with weight loss.

Only about 50% of infected patients develop significant symptoms, but develop serologic evidence of infection.

B. Laboratory Findings

Leukopenia with left shift is characteristic. Thrombocytopenia is unusual and another distinction from rickettsial diseases. Aminotransferase and γ-glutamyl transferase levels are elevated, but significant bilirubin elevation is unusual. Diagnosis is made by finding an antibody response (fourfold rise or single high titer in ELISA; IFA, or CF antibody assay) to the phase II organism. Chronic infection is indicated by antibody against the phase I organism. IgM ELISA and specific PCR tests are also available.

C. Imaging

Pneumonitis occurs in 50% of patients. Multiple segmental infiltrates are common, but the radiographic appearance is not pathognomonic. Consolidation and pleural effusion are rare.

Differential Diagnosis

In the appropriate epidemiologic setting, Q fever should be considered in evaluating causes of atypical pneumonias, such as M pneumoniae, viruses, Legionella, and C pneumoniae. It should also be included among the causes of mild to moderate hepatitis without rash or adenopathy in children with exposure to farm animals.

Treatment & Prognosis

Typically the illness lasts 1–2 weeks without therapy. The course of the uncomplicated illness is shortened with doxycycline. Therapy is continued for several days after the patient becomes afebrile (usually 10–14 days). Quinolones are also effective.

One complication is chronic disease, which often implies myocarditis or granulomatous hepatitis. Meningoencephalitis is a rare complication. C burnetii is also one of the causes of so-called culture-negative endocarditis. Coxiella endocarditis often occurs in the setting of valve abnormalities and is difficult to treat; mortality approaches 50%.

Human Immunodeficiency Virus Infection

Elizabeth J. McFarland, MD

**General Considerations**

Human immunodeficiency virus (HIV) is a retrovirus that primarily infects cells of the immune system, including helper T lymphocytes (CD4 T lymphocytes), monocytes, and macrophages. The function and number of CD4 T lymphocytes and other affected cells are diminished by HIV infection, resulting in profound effects on both humoral and cell-mediated immunity. In the absence of treatment, HIV infection causes generalized immune incompetence, leading to conditions that meet the definition of acquired immunodeficiency syndrome (AIDS) and, eventually, death. The clinical diagnosis of AIDS is made when an HIV-infected child develops any of the opportunistic infections, malignancies, or conditions listed in category C (Table 41–1). In adults and adolescents, the criteria for a diagnosis of AIDS also include an absolute CD4 T-lymphocyte count of 200 cells/μL or less.

Highly active antiretroviral treatment (HAART) can forestall disease progression for many years (≥ 20 years) if taken consistently. However, current treatment fails to eradicate the virus and treatment must be lifelong. The full duration of the favorable outcome of therapy is not yet defined, and it is not known whether adverse effects due to medications and incomplete immune restoration will limit use or impact mortality. Nevertheless, HIV infection can be considered a chronic disease for people with access to treatment rather than an acutely terminal disease.

Early diagnosis offers the opportunity to optimize treatment outcomes for children, adolescents, and adults. Treatment reduces the risk of transmission to others and thus has a public health benefit as well. In an effort to improve early diagnosis, the Centers for Disease Control and Prevention (CDC) recommends that HIV screening tests be conducted in routine health care settings with patient knowledge and right to refuse for patients aged 13–64 years and that all adults should be tested at least once for HIV during their lives. In 2011, the American Academy of Pediatrics recommended at least one-time testing for 16- to 18-year-old adolescents, irrespective of risk factors, living in areas of high (≥ 0.1%) or unknown seroprevalence. In areas of lower seroprevalence, testing is encouraged for all sexually active adolescents and those with other risk factors for HIV infection.

**Epidemiology**

The World Health Organization (WHO) estimated in 2012 that there were 32 million adults and 3.3 million children living with HIV (http://www.who.int/hiv/data/2012_epi_core_en.png). Over 90% live in low- and middle-income countries, primarily sub-Saharan Africa and South and Southeast Asia. Although the number of new infections is estimated to have peaked globally in 1997, infection and mortality rates remain high. Among children younger than 15 years, there were 260,000 new infections and 210,000 deaths in 2012. High rates of new pediatric infections are the result of ongoing mother-to-child transmission (MTCT) in resource-limited settings where access to preventative measures is often not accessible; fewer than 60% of pregnant women received recommend treatment in 2011.

MTCT rates are 20%–40%, overall, if there is no intervention. Transmission occurs in utero, at the time of labor and delivery (peripartum), or during breast-feeding (postnatal transmission). However, MTCT can be reduced to less than 1%–2% with prenatal, perinatal, and postnatal interventions (see Prevention section). The successful implementation of
Table 41–1. Centers for disease control and prevention clinical categories of children with human immunodeficiency virus infection.

Adapted from MMWR Recomm Rep 1994;43(RR-12): 6, 8.

> Mode of Transmission and Pathogenesis

In most cases, HIV infection occurs via mucosal exposure. Information on the early events of HIV infection is based on nonhuman primate models and studies in adults infected by sexual transmission; the events in MTCT are less well studied. At the time of exposure, virus breaches the mucosal barrier, is transported to regional lymph nodes,
replicates, and spreads throughout all lymphoid tissues. Based on nonhuman primate models, replicating virus is found throughout the lymphoid tissue by 48 hours postinfection. During the first days after infection, there is a massive loss of mature CD4 T-helper lymphocytes, especially in the gut mucosa. Approximately 2 weeks after exposure, high levels of HIV are detected in the bloodstream. In adults, the level of viremia declines, without therapy, concurrent with the appearance of an HIV-specific host immune response, and plasma viremia usually reaches a steady-state level about 6 months after primary infection. The amount of virus present in the plasma at that point, known as the “set point,” and thereafter is predictive of the rate of disease progression for the individual. A period of clinical latency usually occurs, lasting from 1 year to more than 12 years, during which the infected person is asymptomatic. However, ongoing viremia and immune activation causes subclinical injury to the immune and other organ systems. The virus and anti-HIV immune responses are in a steady state such that CD4 T-lymphocyte parameters may be stable. Eventually, the balance favors the virus, and the viral burden increases as the CD4 T-lymphocyte count declines, at which time the individual becomes susceptible to opportunistic infections.

Infants with in utero HIV infection have virus detectable in the blood at birth. Those infected peripartum test negative for virus at birth but have virus detected by 2–4 weeks of age. Infant viremia rises steeply, as is also seen in adults reaching a peak at age 1–2 months. In contrast with adults, infants will have only a very gradual decline in plasma viremia that extends to age 4–5 years. Up to 50% of infants will have rapid disease progression to AIDS or death by age 2 years. Although this rapid progression is associated with high-level viremia, measurement of plasma virus and/or CD4 T-lymphocyte parameters do not identify all infants at risk for rapid progression.

PERINATALLY HIV-EXPOSED INFANT

---Clinical Findings---

Newborns with perinatal HIV infection are rarely symptomatic at birth, and there is no recognized primary infection syndrome in these infants. Physical features are not different from uninfected neonates. However, 30%–80% of infected infants have symptoms within the first year of life. Hepatomegaly, splenomegaly, lymphadenopathy, parotitis, and recurrent respiratory tract infections are signs associated with slow progression. Severe bacterial infections, progressive neurologic disease, anemia, and fever are associated with rapid progression. Early ARV therapy can slow or prevent disease progression. Hence, early diagnosis is critical and can be accomplished using laboratory testing during the first months of life.

---Laboratory Diagnosis---

Infants born to HIV-infected mothers will have HIV antibody until 6–18 months of age, regardless of infection status, owing to transplacental passage of maternal antibody. Therefore, diagnosis must be made by direct detection of virus. Age-specific laboratory criteria defining infection status are outlined in Table 41–2. The preferred test for infant diagnosis is detection of HIV DNA or RNA in blood, collectively referred to as nucleic acid amplification testing (NAT). Positive HIV NAT at any age requires repeat testing.

Management and Outcome of the Perinatally HIV-Exposed Infant

HIV-infected infants have a high risk of *Pneumocystis jiroveci* pneumonia (PCP), with the peak incidence at age 2–6 months. Thus, prophylaxis for *P jiroveci* pneumonia is given to infants born to HIV-infected mothers beginning at age 4–6 weeks. PCP prophylaxis may be deferred for infants who are demonstrated to be presumptively HIV-uninfected by age 6 weeks. Infants with ongoing HIV exposure via breast-feeding are recommended to continue PCP prophylaxis until HIV infection has been excluded after cessation of breast-feeding.

During the period of postnatal ARV prophylaxis, some infants have reversible anemia or neutropenia that is usually not clinically significant. Subsequently, children who have been exposed to HIV and to ARV drug prophylaxis (but who remain uninfected) are generally healthy. Ongoing studies have found alterations in some growth, neurocognitive development, immune, and organ function parameters, but their clinical significance is not yet known. Some studies have found symptoms consistent with mitochondrial toxicity; other studies have failed to confirm the findings. There is biological plausibility for this toxicity because the nucleoside analogue drugs used during pregnancy and postnatally to prevent transmission may cause mitochondrial toxicity. The issue remains controversial, but at present it is clear that the benefit of prenatal and postnatal treatment to prevent HIV transmission outweighs the potential risk. Ongoing studies are important to elucidate the affects of in utero and perinatal HIV and ARV exposure.

**ACUTE RETROVIRAL SYNDROME**

Among adolescents and adults with primary acute HIV infection, nonspecific symptoms (e.g., flu- or mild mononucleosis-like illness) beginning 2–4 weeks after exposure occur in 30%–90%, but they are frequently not severe enough to be brought to medical attention. This *acute retroviral syndrome*, with symptoms of fever, malaise, and pharyngitis, is often indistinguishable from other similar viral illnesses. Less common but more distinguishing features are generalized lymphadenopathy, rash, oral and genital ulcerations, aseptic meningitis, and thrush. In the early weeks after acute, behaviorally acquired infection, HIV antibody may be absent. Most patients will seroconvert by 6 weeks after exposure, but occasionally seroconversion does not occur for 3–6 months. When acute HIV infection is suspected, nucleic acid amplification tests will detect HIV infection. Additional information on behaviorally acquired HIV is found in Chapter 44.

**PROGRESSIVE HIV DISEASE**

**A. Clinical Findings**

1. **Disease staging**—The CDC has developed disease staging criteria for HIV-infected children (Table 41–3; see Tables 41–1). The criteria incorporate clinical symptoms ranging from no symptoms to mild, moderate, and severe symptoms (categories N, A, B, and C, respectively) and immunologic categories 1, 2, or 3 (defined by age-adjusted CD4 T-lymphocyte counts) corresponding to no, moderate, or severe immune suppression, respectively. Each child’s disease stage is classified both by clinical and CD4 T-lymphocyte category. The WHO has established a similar clinical staging system that is used widely outside the United States (Table 41–4). Staging criteria characterize the degree of disease progression.

and are predictive of mortality risk for children older than 2 years who are not receiving ARV therapy. Disease stage is used in determining when to initiate ARV therapy.

2. Infections related to immunodeficiency—Progressive immune dysfunction of both humoral and cell-mediated responses results in susceptibility to infections. Bacteremia, especially due to *Streptococcus pneumoniae*, occurs at rates of 3 per 100 child-years without HAART and decreases to 0.36 per 100 child-years with HAART, but this remains at least three times higher than in HIV-uninfected children. Infections with *Mycobacterium tuberculosis* are a major cause of morbidity in countries with high rates of endemic tuberculosis (TB). Given the frequency of coinfection, diagnosis of *M. tuberculosis* in a child is an indication for HIV testing. Likewise, children with HIV infection and their family members should have regular evaluation for *M. tuberculosis* exposure and testing if appropriate. Herpes zoster (shingles) occurs 10 times more frequently among untreated HIV-infected children compared with age-matched healthy children.

Late-stage immunodeficiency is accompanied by susceptibility to a variety of opportunistic pathogens. Pneumonia caused by *P. jiroveci* is a common AIDS-defining diagnosis in children with unrecognized HIV infection who, therefore, are not receiving PCP prophylaxis. The incidence is highest between ages 2 and 6 months and is often fatal during this period. Symptoms are difficult to distinguish from those of viral or atypical pneumonia (see Chapter 43). Persistent candidal mucocutaneous infections (oral, cutaneous, and vaginal) are common. Candidal esophagitis occurs with more advanced disease. Cytomegalovirus (CMV) infections may result in disseminated disease, hepatitis, gastroenteritis, retinitis, and encephalitis. Disseminated infection with *Mycobacterium avium* complex (MAC), presenting with fever, night sweats, weight loss, diarrhea, fatigue, lymphadenopathy, hepatomegaly, anemia, and granulocytopenia, occurs in infected children who have CD4 T-lymphocyte counts below 50–100/μL. A variety of diarrheal pathogens that cause mild, self-limited symptoms in healthy persons may result in severe, chronic diarrhea in HIV-infected persons. These include *Cryptosporidium parvum*, *Microsporidia*, *Cyclospora*, *Isospora belli*, *Giardia lamblia*, and bacterial pathogens. Chronic parovirus infection manifested by anemia can occur.

3. Organ system disease—HIV infection may directly affect a variety of organ systems and produce disease manifestations that include encephalopathy, pneumonitis, hepatitis, diarrhea, hematologic suppression, nephropathy, and cardiomyopathy. On average, HIV-infected children have lower than normal neuropsychological functioning. In many children, neuropsychological deficits do not normalize when ARV therapy is started, despite suppression of viremia. Findings include acquired microcephaly, progressive motor deficit, ataxia, pseudobulbar palsy, and failure to attain (or loss of) developmental milestones.

Lymphoid interstitial pneumonitis, which is common in untreated children with HIV infection, is characterized by a diffuse peribronchial and interstitial infiltrate composed of lymphocytes and plasma cells. It may be asymptomatic or associated with dry cough, hypoxemia, dyspnea or wheezing on exertion, and clubbing of the digits. Children with this disorder frequently have enlargement of the parotid glands and generalized lymphadenopathy.

4. Malignancy—Children with HIV are at increased risk of malignancy. The most commonly occurring tumors are non-Hodgkin lymphomas which may occur at unusual extranodal sites (central nervous system, bone, gastrointestinal tract, liver, or lungs). Human papillomavirus infection of the cervix is more likely to progress to neoplasia, and the rate of progression is not altered by HAART. Carcinoma due to anal human papillomavirus is also a concern. Kaposi sarcoma, a skin/mucous membrane malignancy, common in HIV-infected gay males with advanced disease, is also observed among HIV-infected African children, but it is rare in children in the United States.

B. Laboratory Findings

Established HIV infection in children older than 18 months may be diagnosed by detecting HIV antibody by immunoadsay) or by rapid antibody tests. A confirmatory test, usually a Western blot, immune fluorescent antibody, or a second rapid test from a different manufacturer using a different antigen or test principle, must be performed because rare individuals have cross-reacting antibodies which result in a false-positive ELISA or rapid tests.

The hallmark of HIV disease progression is decline in the absolute number and percentage of CD4 T lymphocytes and an increasing percentage of CD8 T lymphocytes. The CD4 T-lymphocyte values are predictive of the child’s risk of opportunistic infections. Healthy infants and children have CD4 T-lymphocyte numbers that are much higher than in adults; these gradually decline to adult levels by age 5–6 years. Hence, age-adjusted values must be used when assessing a child’s absolute CD4 T-lymphocyte count (see Table 41–3). CD4 T-lymphocyte percentage, which does not vary significantly with age, is also a useful parameter.

Hypergammaglobulinemia of IgG, IgA, and IgM is characteristic. Late in the disease, some individuals may become hypogammaglobulinemic. Hematologic abnormalities (anemia, neutropenia, and thrombocytopenia) may occur due to effects of HIV disease. The cerebrospinal fluid (CSF) may either be normal or may be associated with elevated protein and a mononuclear pleocytosis; HIV nucleic acid testing may be positive in CSF.

C. Differential Diagnosis

HIV infection should be in the differential diagnosis for children being evaluated for immunodeficiency. Depending on the degree of immunosuppression, the presentation in
HIV infection may be similar to that of B-cell (eg, hypogammaglobulinemia), T-cell, or combined immunodeficiencies (eg, severe combined immunodeficiency) (see Chapter 33). HIV infection should also be considered in the evaluation of children with failure to thrive, developmental delay, chronic lung disease, and *M tuberculosis* infection. Chronic HIV infection presenting with generalized lymphadenopathy or hepatosplenomegaly may resemble infections with viruses such as EBV or CMV in children or adolescents. Because blood tests are definitive for the diagnosis of HIV infection, the diagnosis can be readily established or excluded. In rare cases, HIV-infected children with hypogammaglobulinemia have falsely negative antibody tests but may be diagnosed with a nucleic acid–based test. Absence of maternal risk factors or history of negative test results during pregnancy should not dissuade from testing for HIV if the patient has signs consistent with HIV-associated disease since maternal acquisition of HIV late in pregnancy can result in transmission to the infant and may be missed by maternal prenatal HIV testing.

Centers for Disease Control and Prevention: 1994 revised classification system for human immunodeficiency virus infection in children less than 13 years of age. MMWR Recomm Rep 1994;43(RR-12):1 [PMID: 7908403].

---

**Treatment**

HIV infection calls for specific ARV treatment to prevent progressive deterioration of the immune system as well as prophylactic measures at late stages of HIV infection to prevent opportunistic infections. Guidelines for the treatment of HIV and prevention of opportunistic infections developed by US national working groups of pediatric HIV specialists are published by the U.S. Public Health System at: http://www.aidsinfo.nih.gov. The treatment paradigm changes frequently; therefore, prior to initiating treatment, expert consultation should be obtained.

### A. Specific Measures

1. **Principles of HIV treatment**—Treatment of HIV is aimed at suppressing viral replication, thereby increasing/maintaining immune function. ARV treatment that reduces HIV replication is associated with an increase in CD4 T-lymphocyte count and reconstitution of immune function. HIV has a high spontaneous mutation rate that leads to emergence of drug resistance if viral suppression is incomplete. Prevention of resistance mutations requires that virus is not replicating and has no opportunity to generate new mutations. Thus regimens that fully suppress viral replication are key to long-term treatment success.

The current standard regimens are combinations of three drugs, including at least two drugs with different mechanisms of action. Optimally, children on ARV treatment will have laboratory monitoring every 3–4 months to confirm viral suppression and maintenance of CD4 T lymphocytes. If plasma virus becomes consistently detectable (> 400 copies/mL), the underlying cause must be determined, and, if necessary, a change in the medication combination is made. Regular viral load testing is cost-prohibitive in many resource-limited settings, so monitoring the response to ARV treatment must rely on clinical assessment, preferably supplemented with periodic CD4 T-lymphocyte testing. This approach has the risk of continuing a regimen that is not fully suppressive, which may result in accumulating drug resistance mutations. Despite this risk, ARV treatment has resulted in markedly reduced mortality in resource-limited-settings, as it has in settings with viral load monitoring.

Within 3–6 months of successful ARV treatment, circulating HIV declines to below the limit of detection and CD4 T-lymphocyte counts improve and may normalize. However, HIV persists in long-lived resting cells, and cessation of ARV treatment results in resumption of viremia and decline in CD4 T lymphocytes. Therefore, treatment for HIV with currently available modalities must be lifelong.

Strict adherence to the prescribed treatment is critical. A wide range of issues will impact adherence, including convenience and tolerability as well as psychosocial factors such as developmental stage, mental health of child and caregiver, HIV knowledge, and beliefs about treatment. Programs and services that enhance adherence are essential adjuncts of any HIV treatment regimen.

2. **Criteria for initiation of antiretroviral medications**—Many individuals with HIV will have slow disease progression and are asymptomatic for several years. This has led to debate about the optimal timing for initiation of ARV treatment. The current paradigm has shifted toward earlier initiation. Early treatment has advantages of more complete immune reconstitution and reduced risk of HIV disease...
complications but presents potential risks of increased medication toxicity and development of viral resistance. Country-specific treatment guidelines are published and updated when new evidence is available. The criteria for initiation may differ among countries, particularly for resource-rich versus resource-limited settings. WHO recommendations are found at http://www.who.int/hiv/topics/paediatric/en/index.html.

The United States guidelines recommend clinicians consider treatment for all HIV-infected children even at early stages of the disease. Infants diagnosed early have a 30%-50% risk of progression to AIDS or death by age 12–24 months, and there are no tests that reliably identify these rapid progressions. A randomized trial that compared early versus deferred treatment for infants demonstrated a survival benefit for early treatment. Therefore, infants younger than 12 months per US guidelines and 24 months per WHO guidelines, irrespective of clinical or immunologic progression, should begin treatment as soon as possible after diagnosis. For children who have survived longer prior to diagnosis, the risk of rapid progression is less. However, those with evidence of clinical progression (CDC Classification B or C and WHO Stages 3 and 4) or with low CD4 T-lymphocyte counts (category 2 or 3) are at risk of progression within 12 months and should start treatment promptly. High plasma viral load (> 100,000 copies/mL) is also associated with near-term disease progression. For children lacking evidence of disease progression and with low viral loads, deferred treatment may be considered, but most clinicians recommend treatment to reduce the effects of HIV on growth, development, and organ systems.

3. Antiretroviral medications—The U.S. Food and Drug Administration (FDA) has approved 25 drugs categorized into five different drug classes for the treatment of HIV. Many of the drugs have pediatric indications for older children, but pharmacokinetic data and administration forms appropriate for infants and toddlers are not available for many. The mechanism of action of each class is described briefly as follows. Specific drugs in each class are listed in Table 41–5.

A. NUCLEOSIDE AND NUCLEOTIDE REVERSE TRANSCRIPTASE INHIBITORS (NRTIs)—The NRTIs act as nucleotide analogues, which are incorporated into HIV DNA during transcription by the HIV reverse transcriptase. The result is chain termination and failure to complete provirus, preventing integration of HIV genome into cellular DNA.

B. NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS (NNRTIs)—NNRTIs also inhibit HIV DNA synthesis but act at a different site on the viral reverse transcriptase enzyme so that cross-resistance with NRTIs does not occur.

### Table 41–5. U.S. Food and Drug Administration–approved antiretroviral drug class (mechanism of action) and specific drugs in class.

<sup>a</sup>FDA-approved drug for use in pediatric populations.
<sup>b</sup>Available only in combination drug pill with tenofovir, emtricitabine, and cobicistat.

C. PROTEASE INHIBITORS (PIs)—PIs bind the HIV protease and interfere with assembly of infectious virions. Most are given in combination (“boosted”) with a low dose of ritonavir, a second protease inhibitor, which inhibits their metabolism and thereby increases plasma levels.
D. INTEGRASE INHIBITOR (INSTIs)—These drugs inhibit the viral integrase enzyme and prevent integration of HIV-1 nucleic acid into the host genome.

E. ENTRY INHIBITORS—There are two approved entry inhibitors. Enfuvirtide binds to the viral envelope protein and interferes with HIV fusion with the host cell plasma membrane, thereby preventing entry of the virus into the cell. Enfuvirtide must be administered parenterally, which limits tolerability. Maraviroc is a chemokine receptor antagonist that binds one of the HIV coreceptor proteins (CCR5) on the host CD4 T lymphocyte. This blocks viral binding and prevents cell entry for virus that uses that receptor.

4. Complications of antiretroviral medications—ARV treatment may result in a range of adverse effects. Each medication has specific toxicities which are described in detail at http://aidsinfo.nih.gov/contentfiles/lvguidelines/113/appendix-a–pediatric-antiretroviral-drug-information. Common adverse events are gastrointestinal distress, hematologic toxicity (anemia, neutropenia), elevated liver enzymes, dyslipidemia (elevated LDL-cholesterol and triglycerides), glucose intolerance, and abnormal fat distribution (lipodystrophy). Reduced bone mineral content and renal dysfunction may result from drug effects as well as from direct effects of HIV. Several drugs (eg, nevirapine, abacavir) have been associated with severe hepatitis, sometimes associated with a systemic hypersensitivity reaction which may be life threatening if not identified early or upon rechallenge with the same medication. The nucleoside and nucleotide analogues have low-level affinity for the human mitochondrial DNA polymerase. Therefore, these analogues may be incorporated into mitochondrial DNA, which is one mechanism that may lead to adverse effects. Mitochondrial toxicity can result in lactic acidosis, a rare, but potentially fatal, complication. During the initial weeks of treatment, immune restoration may lead to worsening or unmasking of symptoms due to underlining infection with other organisms such as M tuberculosis, an event termed immune reconstitution inflammatory syndrome (IRIS).

B. General Measures

1. Immunizations—Although vaccines are immunogenic in HIV-infected children, the magnitude and durability of the antibody responses to vaccines are often diminished even when administered to a child on effective ARV treatment. Additional doses to boost responses are recommended for some vaccines. More vigorous vaccine responses are found in children with suppressed plasma virus and restored CD4 T-lymphocyte counts. Therefore, for children who were immunized prior to establishment of effective ART, reimmunization should be considered and is recommended for some vaccines (eg, measles-mumps-rubella vaccine).

All inactivated vaccines are safe to administer to HIV-infected children. Annual immunization with inactive influenza vaccine after age 6 months is recommended for HIV-infected children and their close contacts. For live attenuated viral vaccines, the immune status of the child...
must be considered. Varicella and mumps-measles-rubella vaccines (but not the combined measles-mumps-rubella-varicella vaccine) are recommended for HIV-infected children, provided they are only mildly symptomatic (CDC Class N or A; see Table 41–1) and have CD4 T-lymphocyte parameters consistent with CDC category 1 or 2 (see Table 41–3). Current studies are investigating rotavirus vaccine in HIV-exposed and HIV-infected infants. The majority of infants born to HIV-infected women in the United States will be HIV-uninfected, so rotavirus is recommended even though it will be initiated before HIV infection is definitively excluded by early testing. Live attenuated influenza vaccine (LAIV) is not recommended for HIV-infected individuals, although initial studies have not identified safety concerns; close contacts may receive LAIV. Yellow fever vaccine is contraindicated in symptomatic HIV infection or with low CD4 T-lymphocyte count (< 200 cells/μL or CD4 < 15% if age < 6 years), but the benefits may outweigh the risk for asymptomatic individuals with higher CD4 T-lymphocyte counts. Bacille Calmette-Guérin (BCG), oral polio, smallpox, and live typhoid vaccines should not be given to HIV-infected people.

For some vaccines, additional doses or changes to the routine schedule are recommended. Children who have not received Haemophilus influenzae type b (Hib) vaccine and pneumococcal conjugate vaccine (PCV13) series as infants (e.g., immigrants) may benefit from Hib vaccine (two doses between 12 and 59 months of age; one dose after 59 months of age) and two doses of PCV13 (separated by 8 weeks) which may be given after the usual cutoff age of 60 months. The 23-valent pneumococcal polysaccharide vaccine (PPSV) should also be given after age 2 years (and after a PCV13 series), with a second dose given at 3–5 years later. Although HIV infection is not an absolute indication for early administration of meningococcal conjugate vaccine (MCV), because antibody responses to the vaccine may be suboptimal, HIV-infected children who are vaccinated should receive a two-dose primary series. The response to hepatitis B vaccine is particularly unreliable in people with HIV infection. Therefore, a test for hepatitis B surface antibody should be obtained after the three-dose series. If the titer is less than 10 mIU/mL, a second series of three vaccinations is recommended.

2. Prophylaxis for infections—Children with suppressed CD4 T-lymphocyte numbers benefit from primary and secondary prophylactic treatment to prevent opportunistic infections. Children who have had their CD4 T-lymphocyte counts restored with ARV therapy to category 1 or 2 for over 3 months can be taken off prophylactic treatments.

Antibiotic prophylaxis for *P jiroveci* pneumonia has been extremely effective. HIV-infected infants should receive *Pneumocystis* prophylaxis until age 12 months, after which prophylaxis is based on assessment of symptoms and age-adjusted CD4 T-lymphocyte counts every 3 months. Children with low CD4 T-lymphocyte parameters (CDC category 3; see Table 41–3) should continue/begin PCP prophylaxis. Published guidelines from the CDC for *P jiroveci* pneumonia prophylaxis are summarized in Table 41–6.

3. Psychosocial support and mental health—Evaluation and support for psychosocial needs of HIV-affected families is imperative. As with other chronic illnesses, HIV infection affects all family members and also carries additional social stigma. Emotional concerns and financial needs, which are more prominent than medical needs at many stages of the disease process, influence the family’s ability to comply with a medical treatment regimen. HIV-infected children often have comorbid mental health conditions. Rates of attention-deficit/hyperactivity disorder range from 20% to 50% in various studies. Hospital admissions for mental health disorders are more frequent among HIV-infected children. In one study, dual diagnosis of HIV and a mental health disorder occurred in 85% of adolescents who acquired HIV infection through high-risk behaviors. Ideally, care should be coordinated by a team of caregivers that is familiar with HIV disease and its comorbidities, newest therapies, and community resources.

PREVENTION

**Prevention of Mother-to-Child Transmission (PMTCT)**

A number of ARV regimens given to the mother antenatally and during labor and to the infant in the first weeks after birth reduce MTCT rates to 1%–2% without breast-feeding and 3%–5% with breast-feeding. The United States Public Health Services publishes detailed guidelines that are updated frequently (http://aidsinfo.nih.gov/content-files/PerinatalGL.pdf). In the United States, all identified HIV-infected pregnant women are prescribed HAART during pregnancy and labor, infant zidovudine for 6 weeks, and avoidance of breast-feeding. Infants receive combination ARV medications if they are born to women with a higher risk of transmission (no or late maternal ARV treatment and/or lacking viral suppression). Elective C-section prior to labor will also reduce transmission risk for women who have plasma virus 1000 copies/mL or greater. The same interventions are effective in resource-limited settings, but in these countries, breast-feeding has a demonstrated survival value and is therefore recommended. Extended maternal HAART or infant ARV prophylaxis throughout the period of breast-feeding reduces breast milk transmission. A non-HAART maternal regimen is also effective in reducing MTCT and is used in some countries that lack resources for starting HAART in pregnant women who have not had disease progression that qualifies for initiating HAART per country-specific guidelines.

Key to prevention of mother-to-child transmission (PMTCT) is identification of pregnant women with HIV infection. The CDC and the American College of Obstetrics and Gynecology recommend routine HIV testing, with an option to refuse, early in gestation for all pregnant women. Women with ongoing risk factors for HIV acquisition (multiple partners, sexually transmitted diseases [STDs], substance use) should be tested again in late gestation. A woman presenting in labor without previously documented HIV testing should have HIV testing using rapid test assays that yield results within 60 minutes or less. ARV medications, even if implemented as late as 48 hours postpartum, may reduce transmission by as much as 50%.

**Prevention of Sexual Transmission**

Latex condoms used consistently and correctly are highly effective in preventing sexual transmission. Behavioral interventions to increase use of condoms and other safer sex practices are a cornerstone of prevention efforts. However, the success rate with behavioral interventions has been inadequate in most populations. Several biomedical prevention interventions, added to condom use, have demonstrated efficacy in randomized clinical trials. These include (1) male circumcision—approximately 50% reduction in female-to-male transmission; (2) preexposure prophylaxis (PrEP) for HIV-uninfected partners using daily tenofovir—44%–70% reduction for MSM and 60%–70% reduction for discordant heterosexual couples (summaries at http://www.cdc.gov/hiv/prep/); and (3) ARV treatment of HIV-infected individuals—96% reduction in the risk of transmission to HIV-uninfected partners. Finally, postexposure prophylaxis (PEP) using combination ARV drugs initiated within 72 hours after a known HIV exposure was associated with reduced transmission in case-cohort studies. The CDC supports a consult service for questions regarding postexposure prophylaxis (PEP line, 888-488-4911).

**Prevention Through Universal Precautions**

Horizontal transmission (in the absence of sexual contact or injecting drug use) of HIV is exceedingly rare and is associated with exposure of broken skin or mucous membranes to HIV-infected blood or bloody secretions. Several cases have resulted from HIV-infected caregivers feeding children premasticated food; hence, families should be advised against this practice. Saliva, tears, urine, and stool are not contagious if they do not contain gross blood. A barrier protection (eg, latex or rubber gloves or thick pads of fabric or paper) should be used when possible contact with blood or bloody body fluids occurs. Objects that might be contaminated with blood, such as razors or toothbrushes, should not be shared. No special care is required for dishes, towels, toys, or bedsheets. Blood-soiled clothing may be washed routinely with hot water and detergent. Contaminated surfaces may be disinfected easily with a variety of agents, including household bleach (1:10 dilution), some commercial disinfectants (eg, Lysol), or 70% isopropyl alcohol.

The infant or child who is well enough to attend day care or school should not be treated differently from other children. The exception may be a toddler with uncontrollable biting behavior or bleeding lesions that cannot be covered adequately; in these situations, the child may be withheld from group day care. Families may choose to make the school health care provider and/or teacher aware of the diagnosis, but there is no legal requirement that any individual at the school or day...
care center be informed. The parents and child may prefer to keep the diagnosis confidential, because the stigma associated with HIV infection remains difficult to overcome. Because undiagnosed HIV-infected infants and children might be enrolled, all schools and day care centers should have policies with simple guidelines for using universal precautions to prevent transmission of HIV infection in these settings.

Infections: Bacterial & Spirochetal

John W. Ogle, MD
Marsha S. Anderson, MD

BACTERIAL INFECTIONS

GROUP A STREPTOCOCCAL INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Streptococcal pharyngitis:
  - Clinical diagnosis based entirely on symptoms; signs and physical examination unreliable.
  - Throat culture or rapid antigen detection test positive for group A streptococci.
- Impetigo:
  - Rapidly spreading, highly infectious skin rash.
  - Erythematous denuded areas and honey-colored crusts.
  - Group A streptococci are grown in culture from most (not all) cases.

General Considerations

Group A streptococci (GAS) are common gram-positive bacteria producing a wide variety of clinical illnesses, including acute pharyngitis, impetigo, cellulitis, and scarlet fever, the generalized illness caused by strains that elaborate erythrogenic toxin. GAS can also cause pneumonia, septic arthritis, osteomyelitis, meningitis, and other less common infections. GAS infections may also produce nonsuppurative sequelae (rheumatic fever and acute glomerulonephritis).

The cell walls of streptococci contain both carbohydrate and protein antigens. The C-carbohydrate antigen determines the group, and the M- or T-protein antigens determine the specific type. In most strains, the M protein appears to confer virulence, and antibodies developed against the M protein are protective against reinfection with that type.

Almost all GAS are β-hemolytic. These organisms may be carried without symptoms on the skin and in the pharynx, rectum, and vagina. All GAS are sensitive to penicillin. Resistance to erythromycin is common in some countries and has increased in the United States.

Prevention

GAS pharyngitis usually occurs after contact with respiratory secretions of a person infected with GAS. Crowding facilitates spread of GAS and outbreaks of pharyngitis and impetigo can be seen. Prompt recognition and institution of antibiotics may decrease spread. Treatment with antibiotics prevents acute rheumatic fever.

Clinical Findings

A. Symptoms and Signs

1. Respiratory infections

A. Infancy and early childhood (age < 3 years)—The onset is insidious, with mild symptoms (low-grade fever, serous nasal discharge, and pallor). Otitis media is common. Exudative pharyngitis and cervical adenitis are uncommon in this age group.

B. Childhood type—Onset is sudden, with fever and marked malaise and often with repeated vomiting. The pharynx is sore and edematous, and generally there is tonsillar exudate. Anterior cervical lymph nodes are tender and enlarged. Small petechiae are frequently seen on the soft palate. In scarlet fever, the skin is diffusely erythematous and appears sunburned and roughened (sandpaper rash). The rash is most intense in the axillae, groin, and on the abdomen and trunk. It blanches except in the skin folds, which do not blanch and are pigmented (Pastia sign). The rash
usually appears 24 hours after the onset of fever and rapidly spreads over the next 1–2 days. Desquamation begins on the face at the end of the first week and becomes generalized by the third week. Early in the course of infection, there is circumferential pallor and the surface of the tongue is coated white, with the papillae enlarged and bright red (white strawberry tongue). Subsequently desquamation occurs, and the tongue appears beefy red (strawberry tongue). Petechiae may be seen on all mucosal surfaces.

C. Adult type—The adult type of GAS is characterized by exudative or nonexudative tonsillitis with fewer systemic symptoms, lower fever, and no vomiting. Scarlet fever is uncommon in adults.

2. Impetigo—Streptococcal impetigo begins as a papule that vesiculates and then breaks, leaving a denuded area covered by a honey-colored crust. Both *Staphylococcus aureus* and GAS are isolated in some cases. The lesions spread readily and diffusely. Local lymph nodes may become swollen and inflamed. Although the child often lacks systemic symptoms, a high fever and toxicity may be present. If flaccid bullae are noted, the disease is called bullous impetigo and is caused by an epidermolytic toxin-producing strain of *S. aureus.*

3. Cellulitis—The portal of entry is often an insect bite or superficial abrasion. A diffuse, rapidly spreading cellulitis occurs that involves the subcutaneous tissues and extends along the lymphatic pathways with only minimal local suppuration. Local acute lymphadenitis occurs. The child is usually acutely ill, with fever and malaise. In classic erysipelas, the involved area is bright red, swollen, warm, and very tender. The infection may extend rapidly from the lymphatics to the bloodstream.

Streptococcal perianal cellulitis is an entity peculiar to young children. Pain with defecation often leads to constipation, which may be the presenting complaint. The child is afebrile and otherwise well. Perianal erythema, tenderness, and painful rectal examination are the only abnormal physical findings. Scant rectal bleeding with defecation may occur. A perianal swab culture usually yields heavy growth of GAS. A variant of this syndrome is streptococcal vaginitis in prepubertal girls. Symptoms are dysuria and pain; marked erythema and tenderness of the introitus and blood-tinted discharge are seen.

4. Necrotizing fasciitis—This dangerous disease is reported sporadically and may occur as a complication of varicella infection. About 20%–40% of cases are due to GAS; 30%–40% are due to *S. aureus*; and the rest are a result of mixed bacterial infections. The disease is characterized by extensive necrosis of superficial fasciae, undermining of surrounding tissue, and usually systemic toxicity. Initially the skin overlying the infection is tender and pale red without distinct borders, resembling cellulitis. Blisters or bullae may appear. The color deepens to a distinct purple or in some cases becomes pale. Tenderness out of proportion to the clinical appearance, skin anesthesia (due to infarction of superficial nerves), or “woody” induration suggest necrotizing fasciitis. Involved areas may develop mild to massive edema. Early recognition and aggressive debridement of necrotic tissue are essential.

5. Group A streptococcal infections in newborn nurseries—GAS epidemics occur occasionally in nurseries. The organism may be introduced into the nursery from the vaginal tract of a mother or from the throat or nose of a mother or a staff member. The organism then spreads from infant to infant. The umbilical stump is colonized while the infant is in the nursery. Like staphylococcal infections, there may be no or few clinical manifestations while the infant is still in the nursery. Most often, a colonized infant develops a chronic oozing omphalitis days later. The organism may spread from the infant to other family members. Serious and even fatal infections may develop, including sepsis, meningitis, empyema, septic arthritis, and peritonsillitis.

6. Streptococcal sepsis—Serious illness from GAS sepsis is now more common both in children and in adults. Rash and scarlet fever may be present. Prostration and shock result in high mortality rates. Pharyngitis is uncommon as an antecedent illness. Underlying disease is a predisposing factor.

7. Streptococcal toxic shock syndrome (STSS)—Toxic shock syndrome caused by GAS has been defined. Like *S. aureus*–associated toxic shock, multiorgan system involvement is a prominent part of the illness. The diagnostic criteria include (1) isolation of GAS from a normally sterile site, (2) hypotension or shock, and (3) at least two of the following: renal impairment (creatinine > two times the upper limit of normal for age), thrombocytopenia (< 100,000/mm³), or coagulopathy, liver involvement (transaminases > two times normal), acute respiratory distress syndrome, generalized erythematous macular rash or soft tissue necrosis (myositis, necrotizing fasciitis, gangrene). In cases that otherwise meet clinical criteria, isolation of GAS from a nonsterile site (throat, wound, or vagina) is indicative of a probable cause.

B. Laboratory Findings

Leukocytosis with a marked shift to the left is seen early. Eosinophilia regularly appears during convalescence. β-Hemolytic streptococci are cultured from the throat or site of infection. For suspected GAS pharyngitis, the throat should be swabbed and the specimen sent for GAS testing (rapid antigen detection tests and/or culture for GAS) because the clinical features of some viral infections may overlap with the clinical features of GAS. In children and adolescents, negative rapid antigen tests should be backed up by a culture. Patients with positive rapid strep antigen tests do not need a confirmation by throat culture, since the specificities of antigen tests are high. The organism may be
cultured from the skin and by needle aspiration from subcutaneous tissues and other involved sites such as infected nodes. Occasionally blood cultures are positive.

Antistreptolysin O (ASO) titers rise about 150 units within 2 weeks after acute infection. Elevated ASO and anti-DNase B titers are useful in documenting prior throat infections in cases of acute rheumatic fever. The streptozyme test detects antibodies to streptolysin O, hyaluronidase, streptokinase, DNase B, and NADase. It is somewhat more sensitive than the measurement of ASO titers.

Proteinuria, cylindruria, and minimal hematuria may be seen early in children with streptococcal infection. True poststreptococcal glomerulonephritis is seen 1–4 weeks after the respiratory or skin infection.

**Differential Diagnosis**

Streptococcal infection in early childhood must be differentiated from adenovirus and other respiratory virus infections. The pharyngitis in herpangina (coxsackievirus A) is vesicular or ulcerative. Herpes simplex also causes ulcerative lesions, which most commonly involve the anterior pharynx, tongue, and gums. In infectious mononucleosis, the pharyngitis is also exudative, but splenomegaly and generalized adenopathy are typical, and laboratory findings are often diagnostic (atypical lymphocytes, elevated liver enzymes, and a positive heterophile or other serologic test for mononucleosis). Uncomplicated streptococcal pharyngitis improves within 24–48 hours if penicillin is given and by 72–96 hours without antimicrobials.

Group G and group C streptococci are uncommon causes of pharyngitis but have been implicated in epidemics of sore throat in college students. Acute rheumatic fever does not occur following group G or group C infection, although acute glomerulonephritis (AGN) is a complication. *Arcanobacterium hemolyticum* may cause pharyngitis with scarlatina-like or maculopapular truncal rash. In diphtheria, systemic symptoms, vomiting, and fever are less marked; pharyngeal pseudomembrane is confluent and adherent; the throat is less red; and cervical adenopathy is prominent.

Pharyngeal tularaemia causes white rather than yellow exudate. There is little erythema, and cultures for β-hemolytic streptococci are negative. A history of exposure to rabbits and a failure to respond to antimicrobials may suggest the diagnosis. Leukemia and agranulocytosis may be present with pharyngitis and are diagnosed by bone marrow examination.

Scarlet fever must be differentiated from chronic skin infections, such as that complicating childhood eczema. Both acute rheumatic fever and AGN are nonsuppurative complications of GAS infections.

**A. Acute Rheumatic Fever (See Chapter 20)**

**B. Acute Glomerulonephritis**

AGN can follow streptococcal infections of either the pharynx or the skin—in contrast to rheumatic fever, which follows pharyngeal infection only. AGN may occur at any age, even infancy. In most reports of AGN, males predominate by a ratio of 2:1. Rheumatic fever occurs with equal frequency in both sexes. Certain M types are associated strongly with poststreptococcal glomerulonephritis (nephritogenic types). The serotypes producing disease on the skin often differ from those found in the pharynx.

The incidence of AGN after streptococcal infection is variable and has ranged from 0% to 28%. Several outbreaks of AGN in families have involved 50%–75% of siblings of affected patients in 1- to 7-week periods. Second attacks of glomerulonephritis are rare. The median period between infection and the development of glomerulonephritis is 10 days. In contrast, acute rheumatic fever occurs after a median of 18 days.

**C. Poststreptococcal Reactive Arthritis**

Following an episode of group A streptococcal pharyngitis, a reactive arthritis develops in some patients. This reactive arthritis is believed to be due to immune complex deposition and is seen about 1–2 weeks following the acute infection. Patients with poststreptococcal reactive arthritis do not have the full constellation of clinical and laboratory criteria needed to fulfill the Jones criteria for a diagnosis of acute rheumatic fever.

**Treatment**

**A. Specific Measures**

Treatment is directed toward both eradication of acute infection and prevention of rheumatic fever. In patients with pharyngitis, antibiotics should be started early to relieve symptoms and should be continued for 10 days to prevent rheumatic fever. Although early therapy has not been shown to prevent AGN, it seems advisable to treat impetigo promptly in sibling contacts of patients with poststreptococcal nephritis. Neither sulfonamides nor trimethoprim-sulfamethoxazole (TMP-SMX) is effective in the treatment of streptococcal infections. Although topical therapy for impetigo with antimicrobial ointments (especially mupirocin) is as
For infections requiring intravenous therapy, aqueous penicillin G (250,000 U/kg in six divided doses) given intravenously is usually the drug of choice. Cefazolin (100 mg/kg/d intravenously or intramuscularly in three divided doses); clindamycin (30–40 mg/kg/d intravenously in four divided doses); and vancomycin (40 mg/kg/d intravenously in four divided doses) are alternatives in penicillin-allergic patients. Clindamycin should not be used alone empirically for severe, suspected GAS infections because a small percentage of isolates in the United States are resistant to it. Some physicians use both penicillin and clindamycin in patients with necrotizing fasciitis or STSS.

3. Serious GAS disease—Serious GAS infections, such as pneumonia, osteomyelitis, septic arthritis, sepsis, endocarditis, meningitis, and STSS, require parenteral antimicrobial therapy. Penicillin G is the drug of choice for these invasive infections. Clindamycin, in addition to penicillin G, is advocated by many experts for STSS or necrotizing fasciitis. Necrotizing fasciitis requires prompt surgical debridement. In STSS, volume status and blood pressure should be monitored and patients evaluated for a focus of infection, if not readily apparent. Intravenous immune globulin (in addition to antibiotics) has been used in severe cases.

4. Treatment failure—Even when compliance is perfect, organisms will be found in cultures in 5%–35% of children after cessation of therapy. Reculture is indicated only in patients with relapse or recrudescence of pharyngitis or those with a personal or family history of rheumatic fever. Repeat treatment at least once with an oral cephalosporin or clindamycin is indicated in patients with recurrent culture-positive pharyngitis.

5. Prevention of recurrences in rheumatic individuals—The preferred prophylaxis for rheumatic individuals is benzathine penicillin G, 1.2 million units (600,000 units for patients weighing less than 27 kg) intramuscularly every 4 weeks. If the risk of streptococcal exposure is high, every 3-week dosing is preferred. One of the following alternative oral prophylactic regimens may be used: penicillin V, 250 mg twice daily; or sulfadiazine, 0.5 g once a day (if < 27 kg) or 1 g once a day (if > 27 kg). In patients allergic to both penicillin and sulfonamide drugs, erythromycin 250 mg twice daily orally can be used. If carditis is absent, continued prophylaxis is recommended for at least 5 years after the last episode of acute rheumatic fever or until 21 years of age (whichever is longer). Prophylaxis should be continued longer if the risk of contact with persons with GAS is high (eg, parents of school-aged children, pediatric nurses, and teachers). In the presence of carditis without residual heart or valvular disease, a minimum of 10 years after the last episode of acute rheumatic fever or until 21 years of age (whichever is longer) is the minimum duration. If the patient has residual valvular heart disease, many
recommend lifelong prophylaxis. These patients should be at least 10 years from their last episode of rheumatic disease and at least 40 years of age before considering discontinuation of prophylaxis. Those with severe valvular heart disease or with risk of ongoing exposure to GAS may benefit from lifelong prophylaxis. A similar approach to the prevention of recurrences of glomerulonephritis may be used during childhood when there is a suspicion that repeated streptococcal infections coincide with flare-ups of glomerulonephritis.

6. Poststreptococcal reactive arthritis—In contrast to rheumatic fever, nonsteroidal agents may not dramatically improve joint symptoms. However, like patients with rheumatic fever, some patients with poststreptococcal reactive arthritis have developed carditis several weeks to months after their arthritis symptoms began. Patients should be monitored for development of carditis for the next 1–2 years. Some experts recommend antibiotic prophylaxis of these patients (same prophylaxis regimen as in prevention of recurrences of acute rheumatic fever) for 1–2 years and monitoring for signs of carditis (see recommendations for prevention of recurrences of rheumatic fever, above). If carditis does not develop, prophylaxis could then be discontinued. If carditis develops, the patient should be considered to have acute rheumatic fever and prophylaxis continued as described above.

B. General Measures

Acetaminophen is useful for pain or fever. Local treatment of impetigo may promote earlier healing. Crusts should first be soaked off. Areas beneath the crusts should then be washed with soap daily.

C. Treatment of Complications

Rheumatic fever is best prevented by early and adequate penicillin treatment of the streptococcal infection.

D. Treatment of Carriers

Identification and treatment of GAS carriers is difficult. There are no established clinical or serologic criteria for differentiating carriers from the truly infected. Between 10% and 15% of school-aged children in some studies are asymptomatic pharyngeal carriers of GAS. Streptococcal carriers are individuals who do not mount an immune response to the organism and are therefore believed to be at low risk for nonsuppurative sequelae.

Some children receive multiple courses of antimicrobials, with persistence of GAS in the throat, leading to a “streptococcal neurosis” on the part of families.

In certain circumstances, eradication of carriage may be desirable: (1) when a family member has a history of rheumatic fever; (2) when an episode of STSS or necrotizing fasciitis has occurred in a household contact; (3) multiple, recurring, documented episodes of GAS in family members despite adequate therapy; and (4) during an outbreak of rheumatic fever or GAS-associated glomerulonephritis. Clindamycin (20–30 mg/kg/d, given orally in three divided doses; maximum dose 300 mg) or a combination of rifampin (20 mg/kg/d, given orally for 4 days) and penicillin in standard dosage given orally has been used to attempt eradication of carriage.

Prognosis

Death is rare except in infants or young children with sepsis or pneumonia. The febrile course is shortened and complications eliminated by early and adequate treatment with penicillin.

GROUP B STREPTOCOCCAL INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Early-onset neonatal infection:
  - Newborn younger than age 7 days, with rapidly progressing overwhelming sepsis, with or without meningitis.
  - Pneumonia with respiratory failure is frequent; chest radiograph resembles that seen in hyaline membrane disease.
  - Leukopenia with a shift to the left.
  - Blood or cerebrospinal fluid (CSF) cultures growing group B streptococci (GBS).

- Late-onset Infection:
  - Meningitis, sepsis, or other focal infection in a child aged 1–16 weeks with blood or CSF cultures growing GBS.

Prevention

Many women of childbearing age possess type-specific circulating antibody to the polysaccharide antigens for group B Streptococcus (GBS). These antibodies are transferred to the newborn via the placental circulation. GBS carriers delivering
healthy infants have significant serum levels of IgG antibody to this antigen. In contrast, women delivering infants who develop either early- or late-onset GBS disease rarely have detectable antibody in their sera.

Monovalent and bivalent vaccines with type II or III polysaccharide antigens have been studied in pregnant women, with 80%–90% of vaccine recipients developing fourfold or greater increases in GBS capsular polysaccharide type-specific IgG. These reports suggest that a multivalent vaccine could be developed and given to pregnant women to prevent many cases of early-onset GBS disease.

The decline in early-onset GBS disease in young infants is attributed to widespread maternal screening for GBS and intrapartum prophylaxis. The Centers for Disease Control and Prevention (CDC) has issued culture-based maternal guidelines for the prevention of early-onset GBS disease, as well as recommendations for intrapartum prophylaxis and management of babies whose mothers received IAP for prevention of GBS or for chorioamnionitis.

### CDC Recommendations for Prevention of Perinatal GBS Disease

1. All pregnant women should be screened at 35–37 weeks’ gestation with a vaginal and rectal culture for GBS. **Exceptions:** Women with known GBS bacteriuria during the current pregnancy or women who have delivered a previous infant with GBS disease do not need screening—all these women need intrapartum prophylaxis—see Table 42–1.
2. Indications and nonindications for intrapartum antibiotic prophylaxis (IAP) to prevent early-onset group B streptococcal (GBS) disease—see Table 42–1.
3. Algorithm for screening for GBS colonization and use of intrapartum prophylaxis for women with preterm labor (PTL)—see Figure 42–1.
4. Algorithm for screening for GBS colonization and use of intrapartum prophylaxis for women with preterm premature rupture of membranes (pPROM)—see Figure 42–2.

### Table 42–1. Indications and nonindications for intrapartum antibiotic prophylaxis to prevent early-onset group B streptococcal (GBS) disease.

NAAT, nucleic acid amplification tests.

<sup>a</sup>Intrapartum antibiotic prophylaxis is not indicated in this circumstance if a cesarean delivery is performed before onset of labor on a woman with intact amniotic membranes.

<sup>b</sup>Optimal timing for prenatal GBS screening is at 35–37 weeks’ gestation.

<sup>c</sup>Recommendations for the use of intrapartum antibiotics for prevention of early-onset GBS disease in the setting of threatened preterm delivery are presented in Figure 42–1 and 42–2.

<sup>d</sup>If amnionitis is suspected, broad-spectrum antibiotic therapy that includes an agent known to be active against GBS should replace GBS prophylaxis.

<sup>e</sup>NAAT testing for GBS is optional and might not be available in all settings. If intrapartum NAAT is negative for GBS but any other intrapartum risk factor (delivery at <37 weeks’ gestation, amniotic membrane rupture at ≥ 18 hours, or temperature ≥ 100.4°F [≥ 38.0°C]) is present, then intrapartum antibiotic prophylaxis is indicated.

5. Recommended regimens for intrapartum antibiotic prophylaxis for prevention of early-onset GBS disease—see Figure 42–3.

6. Algorithm for secondary prevention of early-onset group B streptococcal (GBS) disease among newborns (management of a newborn whose mother received IAP for prevention of GBS or suspected chorioamnionitis)—see Figure 42–4.

Clinical Findings

The incidence of perinatal GBS disease has declined dramatically since screening of pregnant mothers and provision of intrapartum chemoprophylaxis began. Although most patients with GBS disease are infants younger than age 3 months, cases are seen in infants aged 4–5 months. Serious infection also occurs in women with puerperal sepsis, immunocompromised patients, patients with cirrhosis and spontaneous peritonitis, and diabetic patients with cellulitis. Two distinct clinical syndromes distinguished by differing perinatal events, age at onset, and serotype of the infecting strain occur in infants.

Risk factors for early-onset group B GBS disease include maternal GBS colonization, gestational age less than 37 weeks, rupture of membranes > 18 hours prior to presentation, young maternal age, history of a previous infant with invasive GBS disease, African-American or Hispanic ethnic origin, and low or absent maternal GBS anticapsular antibodies.
A. Early-Onset Infection

“Early-onset” illness is observed in newborns younger than 7 days old. The onset of symptoms in the majority of these infants occurs in the first 48 hours of life, and most are ill within 6 hours. Apnea is often the first sign. Sepsis, shock, meningitis, apnea, and pneumonia are the most common clinical presentations. There is a high incidence of associated maternal obstetric complications, especially premature labor and prolonged rupture of the membranes. Newborns with early-onset disease are severely ill at the time of diagnosis, and more than 50% die. Although most infants with early-onset infections are full-term, premature infants are at increased risk for the disease. Newborns with early-onset infection acquire GBS in utero as an ascending infection or during passage through the birth canal. When early-onset infection is complicated by meningitis, more than 80% of the bacterial isolates belong to serotype III. Postmortem examination of infants with early-onset disease usually reveals pulmonary inflammatory infiltrates and hyaline membranes containing large numbers of GBS.

INFECTIONS: BACTERIAL & SPIROCHETAL

B. Late-Onset Infection

“Late-onset” infection occurs in infants between ages 7 days and 4 months (median age at onset, about 4 weeks). Maternal obstetric complications are not usually associated with late-onset infection. These infants are usually not as ill at the time of diagnosis as those with early-onset disease, and the mortality rate is lower. In recent series, about 37% of patients have meningitis and 46% have sepsis.

Septic arthritis and osteomyelitis, meningitis, occult bactere mia, otitis media, ethmoiditis, conjunctivitis, cellulitis (part icularly of the face or submandibular area), lymphadenitis, breast abscess, empyema, and impetigo have been described. Strains of GBS possessing the capsular type III polysaccharide antigen are isolated from more than 95% of infants with late-onset disease, regardless of clinical manifestations. The exact mode of transmission of the organisms is not well defined.

---

---

* IV, intravenously.
* Broader spectrum agents, including an agent active against GBS, might be necessary for treatment of chorioamnionitis.
† Doses ranging from 2.5 to 3.0 million units are acceptable for the doses administered every 4 hours following the initial dose. The choice of dose within that range should be guided by which formulations of penicillin G are readily available to reduce the need for pharmacies to specially prepare doses.
§ Penicillin-allergic patients with a history of anaphylaxis, angioedema, respiratory distress, or urticaria following administration of penicillin or a cephalosporin are considered to be at high risk for anaphylaxis and should not receive penicillin, ampicillin, or cefazolin for GBS intrapartum prophylaxis. For penicillin-allergic patients who do not have a history of those reactions, cefazolin is the preferred agent because pharmacologic data suggest it achieves effective intraamniotic concentrations. Vancomycin and clindamycin should be reserved for penicillin-allergic women at high risk for anaphylaxis.
¶ If laboratory facilities are adequate, clindamycin and erythromycin susceptibility testing (Box 3) should be performed on prenatal GBS isolates from penicillin-allergic women at high risk for anaphylaxis. If no susceptibility testing is performed, or the results are not available at the time of labor, vancomycin is the preferred agent for GBS intrapartum prophylaxis for penicillin-allergic women at high risk for anaphylaxis.
** Resistance to erythromycin is often but not always associated with clindamycin resistance. If an isolate is resistant to erythromycin, it might have inducible resistance to clindamycin, even if it appears susceptible to clindamycin. If a GBS isolate is susceptible to clindamycin, resistant to erythromycin, and testing for inducible clindamycin resistance has been performed and is negative (no inducible resistance), then clindamycin can be used for GBS intrapartum prophylaxis instead of vancomycin.
C. Laboratory Findings

Culture of GBS from a normally sterile site such as blood, pleural fluid, or CSF provides proof of diagnosis. Frequent false-positive results limit the usefulness of testing for GBS antigen in urine and CSF.

Treatment

Intravenous ampicillin and an aminoglycoside is the initial regimen of choice for newborns with presumptive invasive GBS disease. For neonates 7 days of age or younger with meningitis, the recommended ampicillin dosage is
200–300 mg/kg/d, given intravenously in three divided doses. For infants older than 7 days of age, the recommended ampicillin dosage is 300 mg/kg/d, given intravenously in four divided doses.

Penicillin G can be used alone once GBS is identified and clinical and microbiologic responses have occurred. GBS are less susceptible than other streptococci to penicillin, and high doses are recommended, especially for meningitis. In infants with meningitis, the recommended dosage of penicillin G varies with age: for infants age 7 days or younger, 250,000–450,000 U/kg/d, given intravenously in three divided doses; for infants older than age 7 days, 450,000–500,000 U/kg/d, given intravenously in four divided doses.

A second lumbar puncture after 24–48 hours of therapy is recommended by some experts to assess efficacy. Duration of therapy is 2 weeks for uncomplicated meningitis; at least 4 weeks for osteomyelitis, cerebritis, ventriculitis, or endocarditis; and 10 days for bacteremia. Therapy does not eradicate carriage of the organism.

Although streptococci have been universally susceptible to penicillins, increasing minimum inhibitory concentrations (MICs) have been observed in some isolates. Resistance of isolates to clindamycin and erythromycin has increased significantly worldwide in the past few years.

STREPTOCOCCAL INFECTIONS WITH ORGANISMS OTHER THAN GROUP A OR B

Genera Considerations

Streptococci of groups other than A and B are part of the normal flora of humans and can occasionally cause disease. Group C or group G organisms occasionally produce pharyngitis (with an ASO rise), but without risk of subsequent rheumatic fever. AGN may occasionally occur. Group D streptococci and Enterococcus species are normal inhabitants of the gastrointestinal tract and may produce urinary tract infections, meningitis, and sepsis in the newborn, as well as endocarditis. Nosocomial infections caused by Enterococcus are frequent in neonatal and oncology units and in patients with central venous catheters. Nonhemolytic aerobic streptococci and β-hemolytic streptococci are normal flora of the mouth. They are involved in the production of dental plaque and probably dental caries and are the most common cause of subacute infective endocarditis. Finally, there are numerous anaerobic and microaerophilic streptococci, normal flora of the mouth, skin, and gastrointestinal tract, which alone or in combination with other bacteria may cause sinusitis, dental abscesses, brain abscesses, and intra-abdominal or lung abscesses.

Prevention

Streptococci (other than group A or B) are common normal flora in humans. Some disease caused by these organisms can be prevented by maintaining good oral hygiene. Spread of vancomycin resistant enterococcal strains can be limited by good infection control practices in healthcare environments. Development of resistant strains can also be limited by antimicrobial stewardship. There are no vaccines that prevent infections with these organisms.

Treatment

A. Enterococcal Infections

Enterococcus faecalis and Enterococcus faecium are the two most common and most important strains causing human infections. In general, E. faecalis is more susceptible to antibiotics than E. faecium, but antibiotic resistance is more commonly seen with both species. Invasive enterococcal infections should be treated with ampicillin if the isolate is susceptible or vancomycin in combination with gentamicin. Gentamicin should be discontinued if susceptibility testing demonstrates high-level resistance to gentamicin. Isolates that are resistant to both ampicillin and vancomycin necessitate other therapeutic options.

1. Infections with ampicillin-susceptible enterococci—

Lower tract urinary infections can be treated with oral amoxicillin. Pyelonephritis should be treated intravenously with ampicillin and gentamicin (gentamicin dosing may need to be adjusted for altered renal function). Sepsis or meningitis in the newborn should be treated intravenously with a combination of ampicillin and gentamicin. Peak serum gentamicin levels of 3–5 mcg/mL are adequate as gentamicin is used as a synergistic agent. Endocarditis requires 6 weeks of intravenous treatment. Ampicillin or penicillin in combination with gentamicin is used in susceptible strains. Consult the American Heart Association guidelines for infective endocarditis for treatment recommendations for endocarditis.

2. Infections with ampicillin-resistant or vancomycin-resistant enterococci—

Ampicillin-resistant enterococci are often susceptible to vancomycin (40–60 mg/kg/d in four divided doses). Vancomycin-resistant enterococci are usually also resistant to ampicillin. Linezolid is approved for use in children only for vancomycin-resistant E. faecium infections. Two other agents are approved in adults against certain vancomycin-resistant enterococci. Daptomycin is approved for adults with vancomycin-resistant E. faecalis infections. Quinupristin-dalfopristin is approved for adults...
with vancomycin-resistant *E. faecium* (not effective against *E. faecalis*) infections. Isolates resistant to these newer agents (linezolid, daptomycin, quinupristin-dalfopristin) have been reported. Infectious disease consultation is recommended when use of these drugs is entertained or when vancomycin-resistant enterococcal infections are identified.

**B. Viridans Streptococci Infections (Subacute Infective Endocarditis)**

It is important to determine the penicillin sensitivity of the infecting strain as early as possible in the treatment of viridans streptococcal endocarditis. Resistant organisms are most commonly seen in patients receiving penicillin prophylaxis for rheumatic heart disease. Treatment of endocarditis varies depending on whether the patient has native valves or prosthetic valves/material and whether the organism is penicillin susceptible. Refer to the American Heart Guidelines on Infective Endocarditis for a complete discussion and recommendations.

**C. Other Viridans Streptococci–Related Infections**

Viridans streptococci are normal flora of the gastrointestinal tract, respiratory tract, and the mouth. In many cases, isolation of viridans streptococci from a blood culture is considered to be a “contaminant” in the absence of signs or symptoms of endocarditis or other invasive disease. However, in children who are immunocompromised, have congenital or acquired valvular heart disease, or those who have indwelling lines, these viridans streptococci may be a cause of serious morbidity. About one-third of bacteremias in patients with malignancies may be due to bacteria from the *Streptococcus viridans* group. Mucositis and gastrointestinal toxicity from chemotherapy are among the risk factors for developing disease. Even in children with normal immune systems, viridans streptococci sometimes cause serious infections. For example, viridans streptococci isolated from an abdominal abscess after sustained rupture of the appendix represents a true pathogen. *Streptococcus anginosus*, a member of the *Streptococcus viridans* group, is seen as a cause of intracranial abscess (often as a complication of sinusitis) and abdominal abscesses. In patients with risk factors or signs/symptoms for subacute endocarditis, isolation of one of the members of the *Streptococcus viridans* group should prompt consideration and evaluation for possible endocarditis (see previous section).

Increasing prevalence of antibiotic resistance has been seen over the last 10 years in isolates of the streptococci viridans group. Penicillin resistance varies with geographic region, institution, and the populations tested, but has ranged from 30% to 70% in oncology patients. Cephalosporin resistance is also relatively common. Therefore, it is important to obtain antibiotic susceptibilities to the organism to select effective therapy. Vancomycin, linezolid, and quinupristin-dalfopristin are still effective against most isolates.

**PNEUMOCOCCAL INFECTIONS**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- **Bacteremia:**
  - High fever (> 39.4°C).
  - Leukocytosis (> 15,000/μL).
  - Age 6–24 months.

- **Pneumonia:**
  - Fever, leukocytosis, and tachypnea.
  - Localized chest pain.
  - Localized or diffuse rales. Chest radiograph may show lobar infiltrate (with effusion).

- **Meningitis:**
  - Fever, leukocytosis.
  - Bulging fontanelle, neck stiffness.
  - Irritability and lethargy.

- **All types:**
  - Diagnosis confirmed by cultures of blood, CSF, pleural fluid, or other body fluid.

**General Considerations**

Sepsis, sinusitis, otitis media, pneumonitis, meningitis, osteomyelitis, cellulitis, arthritis, vaginitis, and peritonitis are all part of a spectrum of pneumococcal infection. Clinical findings that correlate with occult bacteremia in ambulatory patients include age (6–24 months), degree of temperature elevation (> 39.4°C), and leukocytosis (> 15,000/μL). Although each of these findings is in itself nonspecific, a combination of them should arouse suspicion. This constellation of findings in a child who has no focus of infection may be an indication for blood cultures and antibiotic therapy. The cause of most of such bacteremic episodes is pneumococci.

*Streptococcus pneumoniae* is a common cause of acute purulent otitis media and is the organism responsible for most cases of acute bacterial pneumonia in children. The disease is indistinguishable on clinical grounds from other bacterial pneumonias. Effusions are common, although frank empyema is less common. Abscesses also occasionally occur.
The incidence rate of pneumococcal meningitis has decreased since incorporation of the pneumococcal conjugate vaccine into the infant vaccine schedule. However, pneumococcal meningitis is still more common than Haemophilus influenzae type b meningitis. Pneumococcal meningitis, sometimes recurrent, may complicate serious head trauma, particularly if there is persistent leakage of CSF. This has led some physicians to recommend the prophylactic administration of penicillin or other antimicrobials in such cases.

Children with sickle cell disease, other hemoglobinopathies, congenital or acquired asplenia, and some immunoglobulin and complement deficiencies are unusually susceptible to pneumococcal sepsis and meningitis. They often have a catastrophic illness with shock and disseminated intravascular coagulation (DIC). Even with excellent supportive care, the mortality rate is 20%–50%. The spleen is important in the control of pneumococcal infection by clearing organisms from the blood and producing an opsonin that enhances phagocytosis. Autosplenectomy may explain why children with sickle cell disease are at increased risk of developing serious pneumococcal infections. Children with cochlear implants are at higher risk for pneumococcal meningitis.

S. pneumoniae rarely causes serious disease in the neonate. Although S. pneumoniae does not normally colonize the vagina, transient colonization does occur. Serious neonatal disease—including pneumonia, sepsis, and meningitis—may occur and clinically is similar to GBS infection.

Historically, penicillin was the agent of choice for pneumococcal infections, and some strains are still highly susceptible to penicillin. However, pneumococci with moderately increased resistance to penicillin are found in most communities. The prevalence of these relatively penicillin-resistant strains in North America varies geographically. Pneumococci with high-level resistance to penicillin and multiple other drugs are increasingly encountered throughout the United States. Pneumococci from normally sterile body fluids should be routinely tested for susceptibility to penicillin as well as other drugs.

Pneumococci have been classified into more than 90 serotypes based on capsular polysaccharide antigens. The frequency distribution of serotypes varies at different times, in different geographic areas, and with different sites of infection.

### Prevention

Two pneumococcal vaccines are licensed for use in children in the United States: 13-valent pneumococcal conjugate vaccine and 23-valent pneumococcal polysaccharide vaccine. The 13-valent pneumococcal conjugate vaccine was licensed in 2010 (replacing the 7-valent pneumococcal vaccine). This vaccine contains antigens from 13 pneumococcal serotypes (1, 3, 4, 5, 6A, 6B, 7F, 9V, 14, 18C, 19A, 10F, and 23F), and is the vaccine currently recommended for routine use in the infant and childhood immunization schedule. Use of the 13-valent conjugate vaccine is important in the prevention of pneumococcal disease because young children (age < 2 years), who are most at risk for the disease, are unable to immunologically mount a predictable response to the 23-valent polysaccharide vaccine. The 13-valent vaccine is currently recommended for (1) infant primary series and childhood booster dosing (replaces the 7-valent vaccine), (2) as a single supplemental dose in healthy children 14–59 months of age who were fully immunized with the 7-valent pneumococcal conjugate vaccine, and (3) use in children aged less than 18 years who have certain underlying medical conditions that put them at high risk for pneumococcal disease. This vaccine and indications for use is discussed in detail in Chapter 10. For children > 2 years of age who are at high risk for invasive pneumococcal disease (sickle cell anemia, anatomic or functional asplenia, HIV-infected children, and persons with certain chronic illnesses), the 23-valent pneumococcal vaccine is recommended 8 weeks following completion of the pneumococcal conjugate vaccine series (see Chapter 10). A second dose of the 23-valent pneumococcal vaccine should be given 5 years after the first dose in children with HIV infection, sickle cell disease, functional or anatomic asplenia, or other immunocompromising conditions.

When a cochlear implant, splenectomy, or immune-compromising therapy is anticipated, the child should complete immunization with the 13-valent pneumococcal conjugate vaccine at least 2 weeks prior to surgery or institution of immune-compromising therapy if possible. If this is not possible due to the urgency of the procedure or therapy, the child should receive immunization as soon as possible thereafter. In children greater than 2 years of age, the 23-valent pneumococcal polysaccharide vaccine can be given at least 8 weeks after completion of the 13-valent pneumococcal conjugate vaccine (see Chapter 10).

### Clinical Findings

#### A. Symptoms and Signs

In pneumococcal sepsis, fever usually appears abruptly, often accompanied by chills. There may be no respiratory symptoms. In pneumococcal sinusitis, mucopurulent nasal discharge may occur. In infants and young children with pneumonia, fever, and tachypnea without auscultatory changes are the usual presenting signs. Respiratory distress is manifested by nasal flaring, chest retractions, and tachypnea. Abdominal pain is common. In older children, the adult form of pneumococcal pneumonia with signs of lobar consolidation may occur, but sputum is rarely bloody. Thoracic pain (from pleural involvement) is sometimes present, but
is less common in children. With involvement of the right hemidiaphragm, pain may be referred to the right lower quadrant, suggesting appendicitis. Vomiting is common at onset but seldom persists. Convulsions are relatively common at onset in infants.

Meningitis is characterized by fever, irritability, convulsions, and neck stiffness. The most important sign in very young infants is a tense, bulging anterior fontanelle. In older children, fever, chills, headache, and vomiting are common symptoms. Classic signs are nuchal rigidity associated with positive Brudzinski and Kernig signs. With progression of untreated disease, the child may develop opisthotonos, stupor, and coma.

**B. Laboratory Findings**

Leukocytosis is often pronounced (20,000–45,000/µL), with 80%–90% polymorphonuclear neutrophils. Neutropenia may be seen early in very serious infections. The presence of pneumococci in the nasopharynx is not a helpful finding, because up to 40% of normal children carry pneumococci in the upper respiratory tract. Large numbers of organisms are seen on Gram-stained smears of endotracheal aspirates from patients with pneumonia. In meningitis, CSF usually shows an elevated white blood cell (WBC) count of several thousand, chiefly polymorphonuclear neutrophils, with decreased glucose and elevated protein levels. Gram-positive diplococci may be seen on some (but not all) stained smears of CSF sediment. Antigen detection tests are not useful. Isolation of *S. pneumoniae* from a normally sterile site (eg, blood, cerebrospinal joint fluid, middle ear fluid) or from a suppurative focus confirms the diagnosis.

**Differential Diagnosis**

There are many causes of high fever and leukocytosis in young infants; 90% of children presenting with these features have a disease other than pneumococcal bacteremia, such as human herpesvirus 6, enterovirus, or other viral infection; urinary tract infection; unrecognized focal infection elsewhere in the body; or early acute shigellosis.

Infants with upper respiratory tract infection who subsequently develop signs of lower respiratory disease are most likely to be infected with a respiratory virus. Hoarseness or wheezing is often present. A radiograph of the chest typically shows perihilar infiltrates and increased bronchovascular markings. Viral respiratory infection often precedes pneumococcal pneumonia; therefore, the clinical picture may be mixed.

Staphylococcal pneumonia may be indistinguishable early in its course from pneumococcal pneumonia. Later, pulmonary cavitation and empyema occur.

In primary pulmonary tuberculosis, children do not have a toxic appearance, and radiographs show a primary focus associated with hilar adenopathy and often with pleural involvement. Miliary tuberculosis presents a classic radiographic appearance.

Pneumonia caused by *Mycoplasma pneumoniae* is most common in children aged 5 years and older. Onset is insidious, with infrequent chills, low-grade fever, prominent headache and malaise, cough, and, often, striking radiographic changes. Marked leukocytosis (>18,000/µL) is unusual.

Pneumococcal meningitis is diagnosed by lumbar puncture. Without a Gram-stained smear and culture of CSF, it is not distinguishable from other types of acute bacterial meningitis.

**Complications**

Complications of sepsis include meningitis and osteomyelitis; complications of pneumonia include empyema, parapneumonic effusion, and, rarely, lung abscess. Mastoiditis, subdural empyema, and brain abscess may follow untreated pneumococcal otitis media. Both pneumococcal meningitis and peritonitis are more likely to occur independently without coexisting pneumonia. Shock, DIC, and Waterhouse-Friderichsen syndrome resembling meningococcemia are occasionally seen in pneumococcal sepsis, particularly in asplenic patients. Hemolytic-uremic syndrome may occur as a complication of pneumococcal pneumonia or sepsis.

**Treatment**

**A. Specific Measures**

All *S. pneumoniae* isolated from normally sterile sites should be tested for antimicrobial susceptibility. The term “nonsusceptible” is used to describe both intermediate and resistant isolates. Strains that are nonsusceptible to penicillin, ceftriaxone (or cefotaxime), and other antimicrobials are increasingly common globally. Antimicrobial susceptibility breakpoints for *S. pneumoniae* to penicillin and ceftriaxone/cefotaxime are based on whether the patient has meningitis and the drug route (oral vs intravenous), see Table 42–2. Therapy of meningitis, empyema, osteomyelitis, and endocarditis due to nonsusceptible *S. pneumoniae* is challenging, because penetration of antimicrobials to these sites is limited. Infectious disease consultation is recommended for advice regarding these problems. For empiric therapy of serious or life-threatening infections pending susceptibility test results, vancomycin and ceftriaxone (or cefotaxime) are recommended.

1. **Bacteremia**—In studies done prior to immunization of young children with conjugated pneumococcal vaccine, 3%–5% of blood cultures in patients younger than 2 years of age yielded *S. pneumoniae*. These percentages decreased with the addition of conjugated pneumococcal vaccine to the vaccine schedule. The current 13-valent pneumococcal vaccine contains antigens to the pneumococcal serotypes that cause about 65% of invasive pneumococcal disease. Many experts
treat suspected bacteremia in children that are not seriously ill with ceftriaxone (50 mg/kg, given intramuscularly or intravenously). Compared with oral amoxicillin (80–90 mg/kg/d), ceftriaxone may reduce fever and the need for hospitalization. However, meningitis occurs with the same frequency despite presumptive therapy. All children with blood cultures that grow pneumococci should be reexamined as soon as possible. The child who has a focal infection, such as meningitis, or who appears septic should be admitted to the hospital to receive parenteral antimicrobials. If the child is afebrile and appears well or mildly ill, outpatient management is appropriate. Severely ill or immunocompromised children, in whom invasive infection with *S pneumoniae* is suspected, should be treated with vancomycin (in addition to other appropriate antibiotics to cover other suspected pathogens). If meningitis is also suspected, use ceftriaxone or cefotaxime in addition to vancomycin until the susceptibilities of the organism are known.

2. **Pneumonia**—For infants (1 month of age or older) with susceptible organisms appropriate regimens include ampicillin (150–200 mg/kg/d intravenously in four divided doses) aqueous penicillin G (250,000–400,000 U/kg/d, given intravenously in four to six divided doses), cefotaxime (50 mg/kg intravenously every 8 hours), or ceftriaxone (50 mg/kg intravenously every 12–24 hours). If susceptibilities are not known and the patient is severely ill or immunocompromised, vancomycin should be used as part of the regimen to provide coverage for penicillin- or cephalosporin-resistant pneumococcus. Once results of susceptibility testing are available, the regimen can be tailored. Mild pneumonia may be treated with amoxicillin (80–90 mg/kg/d) for 7–10 days. Alternative regimens include oral macrolides (resistance may be high) and cephalosporins.

3. **Otitis media**—Most experts recommend oral amoxicillin (80–90 mg/kg/d, divided in two doses) as first-line therapy. The standard course of therapy is 10 days; however, many physicians treat uncomplicated, mild cases in children 6 years of age or older for 5–7 days. Treatment failures may be treated with amoxicillin-clavulanate (80–90 mg/kg/d of the amoxicillin component in the 14:1 formulation), intramuscular ceftriaxone, cefuroxime axetil, or cefdinir. Azithromycin can also be used in patients with type I hypersensitivity reactions to penicillin or cephalosporin, but resistance to macrolides may be high.

4. **Meningitis**—Until bacteriologic confirmation and susceptibility testing are completed, patients should receive vancomycin (60 mg/kg/d, given intravenously in four divided doses) and cefotaxime (225–300 mg/kg/d intravenously in four divided doses), OR vancomycin (see previous dosage) and ceftriaxone (100 mg/kg/d, given intravenously in two divided doses). Patients with serious hypersensitivity to beta-lactam antibiotics allergy (eg, penicillins, cephalosporins) can be treated with a combination of vancomycin (see previous dosage) and rifampin (20 mg/kg/day in two divided doses). Use of vancomycin alone or use of rifampin alone is not recommended. Vancomycin and meropenem is an alternative for penicillin or cephalosporin allergic patients and this regimen provides additional gram-negative coverage until culture and susceptibility results are obtained. Corticosteroids (dexamethasone, 0.6 mg/kg/d, in four divided doses for 4 days) are controversial but are recommended by many experts as adjunctive therapy for pneumococcal meningitis. A repeat lumbar puncture at 24–48 hours should be considered to ensure sterility of the CSF if dexamethasone is given, if resistant pneumococci are isolated, or if the patient is not demonstrating expected improvement after 24–48 hours on therapy.

If the isolate is determined to be penicillin-susceptible, aqueous penicillin G can be administered (300,000–400,000 U/kg/d, given intravenously in four to six divided doses for 10–14 days). Alternatively, use of ceftriaxone or cefotaxime is an acceptable alternative therapy for penicillin- and cephalosporin-susceptible isolates. Consult an infectious disease specialist or the Red Book (American Academy of Pediatrics, 2012) for a complete discussion of pneumococcal meningitis and for therapeutic options for isolates that are nonsusceptible to penicillin or cephalosporins.

*There is no intermediate category for meningitis.*
STAPHYLOCOCCAL INFECTIONS

General Considerations

Staphylococcal infections are common in childhood and range from local mild infections to overwhelming systemic infections. Examples of disease caused by staphylococci include, but are not limited to, furuncles, carbuncles, scalded skin syndrome, osteomyelitis, pyomyositis, septic arthritis, pneumonia, bacteremia, endocarditis, meningitis, and toxic shock syndrome. Staphylococci are the major cause of osteomyelitis and of septic arthritis and are an uncommon but important cause of bacterial pneumonia. A toxin produced by certain strains causes staphylococcal food poisoning. Staphylococci are responsible for many infections of artificial heart valves. Finally, they are found in infections at all ages and in multiple sites, particularly when infection is introduced from the skin or upper respiratory tract or when closed compartments become infected (pericarditis, sinusitis, cervical adenitis, surgical wounds, abscesses in the liver or brain, and abscesses elsewhere in the body).

Staphylococci that do not produce the enzyme coagulase are termed coagulase-negative and are seldom speciated in the clinical microbiology laboratory. Most S aureus strains produce coagulase. S aureus and coagulase-negative staphylococci are normal flora of the skin and respiratory tract. The latter rarely cause disease except in compromised hosts, the newborn, or patients with indwelling lines.

Most strains of S aureus elaborate β-lactamase that confers penicillin resistance. This can be overcome in clinical practice by the use of a cephalosporin or a penicillinase-resistant penicillin, such as oxacillin, nafcillin, cloxacillin, or dicloxacillin. Methicillin-resistant S aureus (MRSA) are resistant in vivo to all of these penicillinase-resistant penicillins and cephalosporins. MRSA has dramatically increased in prevalence globally as both a healthcare-associated and a community-associated pathogen. Healthcare-associated infections are likely to be multidrug resistant. Community-associated MRSA may be susceptible to clindamycin and/or TMP-SMX, but resistance rates to these agents vary widely geographically. MRSA strains with intermediate susceptibility to vancomycin are occurring more frequently and occasionally vancomycin-resistant strains are isolated. The existence of such strains is of concern because of the inherent virulence of most strains of S aureus and because of the limited choices for therapy.

S aureus produces a variety of exotoxins, most of which are of uncertain importance. Two toxins are recognized as playing a central role in specific diseases: exfoliatin and staphylococcal enterotoxin. The former is largely responsible for the various clinical presentations of scalded skin syndrome. Enterotoxin causes staphylococcal food poisoning. The exoprotein toxin most commonly associated with TSS has been termed TSST-1. Panton-Valentine leukocidin (PVL) is an exotoxin produced by some clinical isolates of methicillin-susceptible S aureus (MSSA) and MRSA strains. PVL is a virulence factor that causes leukocyte destruction and tissue necrosis. PVL-producing S aureus strains are often community-acquired, and have most commonly produced boils and abscesses. However, they also have been associated with severe cellulitis, osteomyelitis, and deaths from necrotizing pneumonia in otherwise healthy children and young adults.

Prognosis

In children, case fatality rates of less than 1% should be achieved except for meningitis, where rates of 5%–20% still prevail. The presence of large numbers of organisms without a prominent CSF inflammatory response or meningitis due to a penicillin-resistant strain indicates a poor prognosis. Serious neurologic sequelae, particularly hearing loss, are frequent following pneumococcal meningitis.

Community-associated MRSA and MSSA frequently cause skin and soft tissue infections. Currently MRSA furuncles and abscesses are extraordinarily common in clinical practice. Parents initially may think the child has a spider bite. Skin lesions can be seen anywhere on the body but are commonly seen on the buttocks in infants and young children. Factors that facilitate transmission of MRSA or MSSA include crowding, compromised skin (e.g., eczema), participation on contact sports teams, day care attendance, bare skin contact with surfaces used by others (exercise mats, sauna benches), and sharing towels or other personal items.

*S. aureus* are often found along with streptococci in impetigo. If the strains produce exfoliatin, localized lesions become bullous (bullous impetigo).

Scalded skin syndrome is a toxin-mediated illness caused by exfoliative toxins A and B produced by certain strains of *S. aureus*. The initial infection may begin at any site but is in the respiratory tract in most cases. There is a prodromal phase of erythema, often beginning around the mouth, accompanied by fever and irritability. The involved skin becomes tender, and a sick infant will cry when picked up or touched. A day or so later, exfoliation begins, usually around the mouth. The inside of the mouth is red, and a peeling rash is present around the lips, often in a radial pattern. Generalized, painful peeling may follow, involving the limbs and trunk but often sparing the feet. More commonly, peeling is confined to areas around body orifices. If erythematous but unpeeled skin is rubbed sideways, superficial epidermal layers separate from deeper ones and slough (Nikolsky sign). Generally, if secondary infection does not occur, there is healing without scarring. In the newborn, the disease is termed Ritter disease and may be fulminant.

2. **Osteomyelitis and septic arthritis**—(See Chapter 26.) MRSA invasive disease, including osteomyelitis and septic arthritis is being seen increasingly.

3. **Staphylococcal pneumonia**—Staphylococcal pneumonia in infancy is characterized by abdominal distention, high fever, respiratory distress, and toxemia. It may occur without predisposing factors or after minor skin infections. The organism is necrotizing, producing bronchoalveolar destruction. Pneumatoceles, pyopneumothorax, and empyema are frequently encountered. Rapid progression of disease is characteristic. Frequent chest radiographs to monitor the progress of disease are indicated. Presenting symptoms may be typical of paralytic ileus, suggestive of an abdominal catastrophe.

Invasive MRSA infections are on the rise and increasing numbers of MRSA pneumonias have been reported in all age groups. Many of these reports are in patients who develop MRSA pneumonia as a complication of influenza. MRSA or MSSA pneumonias are rapidly progressive, severe, and often devastating. Complicated pneumonias are frequent including necrotizing pneumonia, pneumatoceles, and/or empyemas. Purulent pericarditis occurs by direct extension in about 10% of cases, with or without empyema.

4. **Staphylococcal food poisoning**—Staphylococcal food poisoning is a result of ingestion of enterotoxin produced by staphylococci growing in uncooked and poorly refrigerated food. The disease is characterized by vomiting, prostration, and diarrhea occurring 2–6 hours after ingestion of contaminated foods.

5. **Staphylococcal endocarditis**—*S. aureus* may produce infection of normal heart valves, of valves or endocardium in children with congenital or rheumatic heart disease, or of artificial valves. About 25% of all cases of endocarditis are due to *S. aureus*. The great majority of artificial heart valve infections involve either *S. aureus* or coagulase-negative staphylococci. Infection usually begins in an extracardiac focus, often the skin. Involvement of the endocardium should be considered when blood cultures grow *S. aureus*, particularly when cultures are persistently positive. Suspicion must be highest in the presence of congenital heart disease, particularly ventricular septal defects with aortic insufficiency but also simple ventricular septal defect, patent ductus arteriosus, and tetralogy of Fallot.

The presenting symptoms in staphylococcal endocarditis are fever, weight loss, weakness, muscle pain or diffuse skeletal pain, poor feeding, pallor, and cardiac decompensation. Signs include splenomegaly, cardiomegaly, petechiae, hematuria, and a new or changing murmur. The course of *S. aureus* endocarditis is rapid, although subacute disease occurs occasionally. Peripheral septic embolization and uncontrollable cardiac failure are common, even when optimal antibiotic therapy is administered, and may be indications for surgical intervention (see later in the section “Staphylococcal Endocarditis”).

6. **Toxic shock syndrome**—TSS is characterized by fever, blanching erythema, diarrhea, vomiting, myalgia, prostration, hypotension, and multiorgan dysfunction. It is due to *S. aureus* focal infection, usually without bacteremia. Large numbers of cases have been described in menstruating adolescents and young women using vaginal tampons. TSS has also been reported in boys and girls with focal staphylococcal infections and in individuals with wound infections due to *S. aureus*. Additional clinical features include sudden onset; conjunctival suffusion; mucosal hyperemia; desquamation of skin on the palms, soles, fingers, and toes during convalescence; DIC in severe cases; renal and hepatic functional abnormalities; and myolysis. The mortality rate with early treatment is now about 2%. Recurrences are seen during subsequent menstrual periods in as many as 60% of untreated women who continue to use tampons.
Recurrences occur in up to 15% of women given antistaphylococcal antibiotics who stop using tampons. The disease is caused by strains of \textit{S. aureus} that produce TSST-1 or one of the related enterotoxins.

7. Coagulase-negative staphylococcal infections—
Local and systemic coagulase-negative staphylococcal infections occur primarily in immunocompromised patients, high-risk newborns, and patients with plastic prostheses or catheters. Coagulase-negative staphylococci are the most common nosocomial pathogen in hospitalized low-birth-weight neonates in the United States. Intravenous administration of lipid emulsions and indwelling central venous catheters are risk factors contributing to coagulase-negative staphylococcal bacteremia in newborn infants. In patients with an artificial heart valve, a Dacron patch, a ventriculoperitoneal shunt, or a central venous catheter, coagulase-negative staphylococci are a common cause of sepsis or catheter infection, often necessitating removal of the foreign material and protracted antibiotic therapy. Because blood cultures are frequently contaminated by this organism, diagnosis of genuine localized or systemic infection is often difficult.

B. Laboratory Findings
Moderate leukocytosis (15,000–20,000/μL) with a shift to the left is occasionally found, although normal counts are common, particularly in infants. The sedimentation rate is elevated. Blood cultures are frequently positive in systemic staphylococcal disease and should always be obtained when it is suspected. Similarly, pus from sites of infection should always be aspirated or obtained surgically, examined with Gram stain, and cultured both aerobically and anaerobically. There are no useful serologic tests for staphylococcal disease.

\(\text{\textbf{Differential Diagnosis}}\)
Staphylococcal skin disease takes many forms; therefore, the differential list is long. Staphylococcal skin abscesses, furuncles, and carbuncles are often confused initially with a spider bite. Bullous impetigo must be differentiated from chemical or thermal burns, from drug reactions, and, in the very young, from the various congenital epidermolytic syndromes or even herpes simplex infections. Staphylococcal scalded skin syndrome may resemble scarlet fever, Kawasaki disease, Stevens-Johnson syndrome, erythema multiforme, and other drug reactions. A skin biopsy may be critical in establishing the diagnosis. Varicella lesions may become superinfected with exfoliatin-producing staphylococci and produce a combination of the two diseases (bullous varicella).

Severe, rapidly progressing pneumonia with formation of abscesses, pneumatoceles, and empyemas is typical of \textit{S. aureus} infection and GAS but may occasionally be produced by pneumococci, \textit{H. influenzae}, and GAS.

Staphylococcal food poisoning is often epidemic. It is differentiated from other common-source gastroenteritis syndromes (\textit{Salmonella}, \textit{Clostridium perfringens}, and \textit{Vibrio parahaemolyticus}) by the short incubation period (2–6 hours), the prominence of vomiting (as opposed to diarrhea), and the absence of fever.

Endocarditis is suspected with \textit{S. aureus} bacteremia, particularly when a significant heart murmur or preexisting cardiac disease is present (see Chapter 20).

Newborn infections with \textit{S. aureus} can resemble infections with streptococci and a variety of gram-negative organisms. Umbilical and respiratory tract colonization occurs with many pathogenic organisms (GBS, \textit{Escherichia coli}, and \textit{Klebsiella}), and both skin and systemic infections occur with virtually all of these organisms.

TSS must be differentiated from Rocky Mountain spotted fever, leptospirosis, Kawasaki disease, drug reactions, adenovirus, and measles (see also Table 42–3).
# Treatment

## A. Specific Measures

Community-acquired MRSA infections are on the rise. The incidence of community-acquired MRSA isolates varies greatly geographically, but in many communities in the United States MRSA is the most common pathogen isolated from patients with skin and soft tissue infections. For empiric coverage of potentially life-threatening infections with suspected *S. aureus* (in which susceptibilities are not known) initial therapy should include vancomycin in combination with either nafcillin or oxacillin (in addition to appropriate antibiotic therapy for other suspected pathogens). Antibiotic therapy can then be adjusted based on identification of the organism and susceptibility results.

Currently, most community-acquired MRSA strains are susceptible to TMP-SMX and some are susceptible to clindamycin. Less serious infections in nontoxic patients may be initially treated using one of these agents while awaiting cultures and susceptibility data. Knowledge of the community MRSA susceptibility patterns is useful in guiding empiric therapy while awaiting susceptibility test results.

For MSSA strains, a β-lactamase-resistant penicillin is the drug of choice (oxacillin or nafcillin). In serious systemic disease, in osteomyelitis, and in the treatment of large abscesses, intravenous therapy is indicated initially (oxacillin or nafcillin, 100–150 mg/kg/d in four divided doses). In serious or life-threatening illness, consultation with an infectious disease physician is recommended.

Cephalosporins may be considered for MSSA infections in patients with a history of penicillin sensitivity unless there is a history of type 1 hypersensitivity reaction (ie, anaphylaxis, wheezing, edema, and hives). Cefazolin, 100–150 mg/kg/d, given intravenously in three divided doses, or cephalexin, 50–100 mg/kg/d, given orally in four divided doses, can be used once a child is able to take oral antibiotics. The third-generation cephalosporins should not generally be used for staphylococcal infections.

For serious *S. aureus* infections, initial therapy with vancomycin (15 mg/kg/dose intravenously every 6 hours) plus nafcillin or oxacillin is recommended until susceptibilities are available. For nosocomially acquired MRSA infections, vancomycin should be used until results of susceptibility testing are available to guide therapy (isolates are frequently clindamycin and TMP-SMX–resistant). Infections due to MRSA do not respond to cephalosporins despite in vitro testing that suggests susceptibility. For treatment of meningitis, vancomycin must be given in higher doses (60 mg/kg/d divided into four doses). The addition of rifampin is advocated by some (rifampin should not be used alone to treat this condition).

### 1. Skin infections—Treatment of skin and soft tissue infections depends, in part, on the extent of the lesion, immunocompetence of the host, and the toxicity of the patient. Afebrile, well-appearing patients with small abscesses may do well with incision and drainage (with or without the addition of oral antimicrobials). More serious infections or infections in immunocompromised patients should be treated more aggressively. Hospitalization and intravenous antibiotics may be required. Culture and susceptibility testing help guide therapy regardless of whether the patient initially is started on antibiotics. Results of these tests facilitate therapeutic decisions in cases in which patients do not respond to initial management or empiric intravenous antibiotic therapy was initiated.

For patients who are not sick enough to require hospitalization or intravenous therapy, selection of the best empiric antimicrobial depends on local rates of MRSA and local susceptibilities. β-Lactam antibiotics, such as penicillins and cephalosporins, can no longer be depended on as single agents for the majority of cases in communities with high MRSA rates. TMP-SMX and clindamycin (depending on local susceptibility patterns) may be used for empiric staphylococcal coverage. However, GAS are generally resistant to TMP-SMX and in a small number of cases may also be resistant to clindamycin. Many clinicians empirically use a combination of TMP-SMX and cefazolin for initial treatment until susceptibilities are known. Linezolid is another option, although the cost of this drug is high.

### 2. Osteomyelitis and septic arthritis—Treatment should be begun intravenously, with antibiotics selected to cover the most likely organisms (staphylococci in hematogenous osteomyelitis; meningoccci, pneumococci, staphylococci in children younger than age 3 years with septic arthritis; staphylococci and gonococci in older children with septic arthritis). Knowledge of local MRSA rates will help guide empiric therapy. Antibiotic levels should be kept high at all times.

Clinical studies support the use of intravenous treatment for osteomyelitis until fever and local symptoms and signs have subsided—usually at least 3–5 days—followed by oral therapy. For both osteomyelitis and joint infections, good compliance with oral therapy is important for successful cure.

For methicillin-susceptible *S. aureus* strains, nafcillin, oxacillin, or cefazolin can be used for intravenous therapy. Clindamycin is an alternative agent if the organism is susceptible and the patient does not have a severe or life-threatening infection or ongoing bacteremia. Dicloxacillin, 100–150 mg/kg/d in four divided doses or cephalexin, 100–150 mg/kg/d in four divided doses) can be used when the patient is ready for oral therapy.

For MRSA osteomyelitis, vancomycin can be used initially while awaiting final susceptibilities. Antibiotic regimens for MRSA osteomyelitis should be based on susceptibility results; isolates may be susceptible to clindamycin or linezolid, but susceptibility patterns vary geographically.
In arthritis, where drug diffusion into synovial fluid is good, intravenous therapy need be given only for a few days, followed by adequate oral therapy for at least 3 weeks.

The C-reactive protein (in the first or second week after therapy is started) and the erythrocyte sedimentation rate (usually measured weekly) are good indicators of response to therapy. Surgical drainage of osteomyelitis or septic arthritis is often required (see Chapter 26).

3. Staphylococcal pneumonia—In the few areas of the country where MRSA is not prevalent, or if the isolate is known to be MSSA, nafcillin and oxacillin are the usual drugs of choice. Vancomycin can be used empirically until results of cultures and susceptibility tests are obtained if MRSA rates are high. In sicker patients, vancomycin plus nafcillin or vancomycin plus oxacillin can be used (in addition to coverage of other pathogens) until the etiologic agent and susceptibilities are established. Linezolid has been reported to be as efficacious as vancomycin for the treatment of resistant gram-positive pneumonia and soft tissue infections.

Empyema and pyopneumothorax require drainage. The choice of chest tube versus thoracoscopic drainage depends on the practitioner’s experience and skill. If staphylococcal pneumonia is treated promptly and empyema drained, resolution in children often is complete.

4. Staphylococcal food poisoning—Therapy is supportive and usually not required except in severe cases or for small infants with marked dehydration.

5. Staphylococcal endocarditis—The treatment of staphylococcal endocarditis depends on whether the patient has a prosthetic valve or material in the heart and on the susceptibilities of the organism. Please see the American Heart Association’s Guidelines on Infective Endocarditis: Diagnosis and Management and consult an infectious disease physician for this serious and sometimes complicated problem. High-dose, prolonged parenteral treatment is indicated. Methicillin-susceptible isolates, in the absence of prosthetic material, are often treated with oxacillin or nafcillin. Some experts also recommend addition of gentamicin for the first 3–5 days. In penicillin-allergic patients (type 1 hypersensitivity or anaphylaxis) or patients with MRSA isolates, vancomycin should be used.

For patients (without penicillin allergy) with prosthetic material in the heart and who have methicillin susceptible isolates, nafcillin (or oxacillin) plus rifampin is used; gentamicin is added during the first 2 weeks. For patients with MRSA endocarditis with prosthetic material present, vancomycin plus rifampin is recommended; gentamicin is added for the first 2 weeks. Therapy lasts in all instances for at least 6 weeks.

Occasionally, medical treatment fails. Signs of treatment failure are (1) recurrent fever without apparent treatable other cause (eg, thrombophlebitis, respiratory or urinary tract infection, drug fever), (2) persistently positive blood cultures, (3) intractable and progressive congestive heart failure, and (4) recurrent (septic) embolization. In such circumstances—particularly (2), (3), and (4)—evaluation for valve replacement becomes necessary. Antibiotics are continued for at least another 4 weeks. Persistent or recurrent infection may require a second surgical procedure.

6. Toxic shock syndrome—Treatment is aimed at expanding blood volume, maintaining perfusion pressure with inotropic agents, ensuring prompt drainage of a focus of infection (or removal of tampons or foreign bodies), and giving intravenous antibiotics.

Vancomycin, in addition to a β-lactam antibiotic (oxacillin or nafcillin), can be used for empiric therapy. Many experts also add clindamycin, since clindamycin is a protein synthesis inhibitor and may turn off toxin production. Clindamycin should not be used empirically as a single agent until susceptibilities (when an isolate grows) are known; some strains of *S aureus* are clindamycin-resistant.

Intravenous immune globulin has been used as adjunctive therapy. Some experts believe that corticosteroid therapy may be effective if given to patients with severe illness early in the course of their disease.

7. Vancomycin-resistant *S aureus* infections (VRSA)—Reports of VRSA isolates are rare but are likely to increase in frequency in the future. Such isolates are sometimes susceptible to clindamycin or TMP-SMX. If not, therapeutic options are limited and include use of quinupristin-dalfopristin, linezolid, or daptomycin, assuming the strain is susceptible to these agents. Quinupristin-dalfopristin is not FDA approved for children less than 16 years of age; daptomycin is not FDA approved for children less than 18 years of age. Consultation with an infectious disease specialist is recommended.

8. Coagulase-negative staphylococcal infections—Bacteremia and other serious coagulase-negative staphylococcal infections are treated initially with vancomycin, with susceptibility results guiding subsequent therapy. Coagulase-negative staphylococci are uncommonly resistant to vancomycin (see Chapter 39 for dosing).

Meningococcal Infections

General Considerations

Meningococci (Neisseria meningitidis) may be carried asymptptomatically for many months in the upper respiratory tract. Less than 1% of carriers develop disease. Meningitis and sepsis are the two most common forms of illness, but septic arthritis, pericarditis, pneumonia, chronic meningococcemia, otitis media, conjunctivitis, and vaginitis also occur. The incidence of invasive diseases in the United States is about 1.2 cases per 100,000 people. An estimated 2400–3000 cases occur in the United States annually. The highest attack rate for meningococcal meningitis is in the first year of life. There also is an elevated attack rate during the teen years. The development of irreversible shock with multiorgan failure is a significant factor in the fatal outcome of acute meningococcal infections.

Meningococci are gram-negative organisms containing endotoxin in their cell walls. Endotoxins cause capillary vascular injury and leak as well as DIC. Meningococci are classified serologically into groups: A, B, C, Y, and W-135 are the groups most commonly implicated in systemic disease. The serologic groups serve as markers for studying outbreaks and transmission of disease. Currently in the United States, serogroups B accounts for 20% of cases, serogroup C accounts for 30% of cases and, serogroup Y account for about 48% of cases. Serogroup A causes periodic epidemics in developing countries, but only occasionally is associated with cases of meningococcal disease in the United States. Sulfonamide resistance is common in non–serotype-A strains. N meningitidis with increased MICs to penicillin G are reported from South Africa and Spain. A small number of these isolates are reported in the United States. The resistance in these strains is low-level and not due to β-lactamase. Resistant isolates are susceptible to third-generation cephalosporins. Few isolates are resistant to rifampin.

Children develop immunity from asymptomatic carriage of meningococci (usually nontypeable, nonpathogenic strains) or other cross-reacting bacteria. Patients deficient in one of the late components of complement (C6, C7, C8, or C9) are uniquely susceptible to meningococcal infection, particularly group A meningococci. Deficiencies of early and alternate pathway complement components also are associated with increased susceptibility.

Prevention

A. Chemoprophylaxis

Household contacts, day care center contacts, and hospital personnel directly exposed to the respiratory secretions of patients are at increased risk for developing meningococcal infection and should be given chemoprophylaxis with rifampin. The secondary attack rate among household members is about 1000 times the attack rate in the general population. Children between the ages of 3 months and 2 years are at greatest risk, presumably because they lack protective antibodies. Secondary cases may occur in day care centers and in classrooms. Hospital personnel are not at increased risk unless they have had contact with a patient’s oral secretions, for example, during mouth-to-mouth resuscitation, intubation, or suctioning procedures. Approximately 50% of secondary cases in households have their onset within 24 hours of identification of the index case. Exposed contacts should be notified promptly. If they are febrile, they should be fully evaluated and given high doses of penicillin or another effective antimicrobial pending the results of blood cultures.

All high-risk contacts should receive chemoprophylaxis for meningococcal disease as soon as an index case is identified. High-risk contacts are defined as:

- All household contacts (especially children < 2 years of age)
- Persons with child care or preschool contact with the index patient at any time in the 7 days prior to illness onset
- Persons with direct exposure to index patients secretions (sharing of drinks, straws, cigarettes, toothbrushes, eating utensils, kissing, etc) at any time in the 7 days prior to illness onset
- Persons who have performed mouth-to-mouth resuscitation or performed unprotected endotracheal intubation of the index patient at any time in the 7 days prior to illness onset
- Persons who have slept in the same dwelling as the index patient within 7 days of illness onset
- Passengers who were seated directly next to the index patient on a flight of more than 8 hours duration

The most commonly used agent for meningococcal chemoprophylaxis is rifampin, given orally in the following dosages twice daily for 2 days: 600 mg for adults; 10 mg/kg for children older than 1 month (maximum dosage 600 mg); and 5 mg/kg for infants younger than 1 month. Rifampin may stain a patient’s tears (and contact lenses), sweat, and urine orange; it may also affect the reliability of oral contraceptives,
and alternative contraceptive measures should therefore be employed when rifampin is administered. Rifampin should not be given to pregnant women. Instead, intramuscular ceftriaxone is the preferred agent: 125 mg given as a single dose if the patient is younger than 15 years; 250 mg given as a single dose if older than 15 years. Penicillin and most other antibiotics (even with parenteral administration) are not effective chemoprophylactic agents, because they do not eradicate upper respiratory tract carriage of meningococci. Ciprofloxacin (20 mg/kg as a single dose, maximum dose 500 mg) effectively eradicates nasopharyngeal carriage in adults and children but is not approved for use in children or in pregnant women. Throat cultures to identify carriers are not useful.

B. Vaccine

Two types of vaccines are currently licensed in the United States. A quadrivalent polysaccharide vaccine (MSPV-4) prepared from purified meningococcal polysaccharides (A, C, Y, and W-135) is available in the United States for children and adults 2 years older of age. Quadrivalent meningococcal conjugate vaccines (see Chapter 10) are licensed for use in children and adults between the ages of 2 months and 55 years, and meningococcal conjugate vaccine is preferred over the polysaccharide vaccine. In general, conjugate vaccines provide longer-lasting immunity and a more robust immune response than polysaccharide vaccines. See Chapter 10 for a discussion on meningococcal vaccines.

Clinical Findings

A. Symptoms and Signs

Many children with clinical meningococcemia also have meningitis, and some have other foci of infection. All children with suspected meningococcemia should have a lumbar puncture.

1. Meningococcemia—A prodrome of upper respiratory infection is followed by high fever, headache, nausea, marked toxicity, and hypotension. Purpura, petechiae, and occasionally bright pink, tender macules or papules over the extremities and trunk are seen. The rash usually progresses rapidly. Occasional cases lack rash. Fulminant meningococcemia (Waterhouse-Friderichsen syndrome) progresses rapidly and is characterized by DIC, massive skin and mucosal hemorrhages, and shock. This syndrome also may be caused by *H. influenzae*, *S. pneumoniae*, or other bacteria. Chronic meningococcemia is characterized by periodic bouts of fever, arthralgia or arthritis, and recurrent petechiae. Splenomegaly often is present. Patients may be free of symptoms between bouts. Chronic meningococcemia occurs primarily in adults and mimics Henoch-Schönlein purpura.

2. Meningitis—In many children, meningococcemia is followed within a few hours to several days by symptoms and signs of acute purulent meningitis, with severe headache, stiff neck, nausea, vomiting, and stupor. Children with meningitis generally fare better than children with meningococcemia alone, probably because they have survived long enough to develop clinical signs of meningitis.

B. Laboratory Findings

The peripheral WBC count may be either low or elevated. Thrombocytopenia may be present with or without DIC (see Chapter 30). If petechial or hemorrhagic lesions are present, meningococci can sometimes be seen microscopically in tissue fluid expressed from a punctured lesion. CSF is generally cloudy and contains more than 1000 WBCs/μL, with many polymorphonuclear neutrophils and gram-negative intracellular diplococci. A total hemolytic complement assay may reveal absence of late components as an underlying cause.

Differential Diagnosis

The skin lesions of *H. influenzae* or pneumococci, enterovirus infection, endocarditis, leptospirosis, Rocky Mountain spotted fever, other rickettsial diseases, Henoch-Schönlein purpura, and blood dyscrasias may be similar to meningococcemia. Severe *S. aureus* sepsis has been reported in some patients to present with purpura. Other causes of sepsis and meningitis are distinguished by appropriate Gram stain and cultures.

Complications

Meningitis may lead to permanent central nervous system (CNS) damage, with deafness, convulsions, paralysis, or impaired intellectual function. Hydrocephalus may develop and requires ventriculoperitoneal shunt. Subdural collections of fluid are common but usually resolve spontaneously. Extensive skin necrosis, loss of digits or extremities, intestinal hemorrhage, and late adrenal insufficiency may complicate fulminant meningococcemia.

Treatment

Blood cultures should be obtained for all children with fever and purpura or other signs of meningococcemia, and antibiotics should be administered immediately as an emergency procedure. There is a good correlation between survival rates and prompt initiation of antibiotic therapy. Purpura and fever should be considered a medical emergency.

Children with meningococcemia or meningococcal meningitis should be treated as though shock were imminent even if their vital signs are stable when they are first seen. If hypotension already is present, supportive measures should be aggressive, because the prognosis is grave in such situations. Treatment should be started emergently and in an intensive care setting but should not be delayed for the sake...
of transporting the patient. Shock may worsen following antimicrobial therapy due to endotoxin release. To minimize the risk of nosocomial transmission, patients should be placed in respiratory isolation for the first 24 hours of antibiotic treatment.

A. Specific Measures

Antibiotics should be initiated promptly. Because other bacteria, such as S pneumoniae, S aureus, or other gram-negative organisms, can cause identical syndromes, initial therapy should be broad. Vancomycin and cefotaxime (or ceftriaxone) are preferred initial coverage. Once N meningitidis has been isolated, penicillin G, cefotaxime, or ceftriaxone intravenously for 7 days are the drugs of choice. Relative penicillin resistance is uncommon but has been reported in the United States.

B. General Measures

Most cases of invasive meningococcal disease are treated with intravenous antibiotics for 7 days.

1. Cardiovascular—(See Chapter 14 for management of septic shock.) Corticosteroids are not beneficial. Sympathetic blockade and topically applied nitroglycerin have been used locally to improve perfusion.

2. Hematologic—Adjunctive therapy with heparin is controversial. Because hypercoagulability is frequently present in patients with meningococemia, some experts believe heparin should be considered for those with DIC. Recombinant tissue plasminogen activator, concentrated antithrombin III, and recombinant protein-C infusions have been tried experimentally to reverse coagulopathy (see Chapter 30 for the management of DIC).

Prognosis

Unfavorable prognostic features include shock, DIC, and extensive skin lesions. The case fatality rate in fulminant meningococcemia is over 30%. In uncomplicated meningococcal meningitis, the fatality rate is much lower (10%–20%).

Centers for Disease Control and Prevention: Updated recommendations for use of meningococcal conjugate vaccines—Advisory Committee on Immunization Practices (ACIP), 2010. MMWR 2011;60:72–76.

GONOCOCCAL INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Purulent urethral discharge with intracellular gram negative diplococci on smear in male patients (usually adolescents).
- Purulent, edematous, sometimes hemorrhagic conjunctivitis with intracellular gram-negative diplococci in 2- to 4-day-old infants.
- Fever, arthritis (often polyarticular) or tenosynovitis, and maculopapular peripheral rash that may be vesiculopustular or hemorrhagic.
- Positive culture of blood, pharyngeal, or genital secretions.

General Considerations

Neisseria gonorrhoeae is a gram-negative diplococcus. Although morphologically similar to other neisseriae, it differs in its ability to grow on selective media and to ferment carbohydrates. The cell wall of N gonorrhoeae contains endotoxin, which is liberated when the organism dies and is responsible for the production of a cellular exudate. The incubation period is short, usually 2–5 days.

Nearly 310,000 cases of gonorrhea were reported in the United States in 2010. Gonococcal disease in children may be transmitted sexually or nonsexually. Prepubertal gonococcal infection outside the neonatal period should be considered presumptive evidence of sexual contact or child abuse. Prepubertal girls usually manifest gonococcal vulvovaginitis because of the neutral to alkaline pH of the vagina and thin vaginal mucosa.

In the adolescent or adult, the workup of every case of gonorrhea should include a careful and accurate inquiry into the patient’s sexual practices, because pharyngeal infection resulting from oral sex must be detected if present and may be difficult to eradicate. Efforts should be made to identify and provide treatment to all sexual contacts. When prepubertal children are infected, epidemiologic investigation should be thorough.

Antimicrobial-resistant gonococci are a serious problem. N gonorrhoeae infections resistant to tetracyclines, penicillins, and fluoroquinolones are common. Fluoroquinolone antimicrobials are no longer recommended for therapy in the United States. In some cases, clinicians will have very limited choices for therapy. Many clinical laboratories do not routinely perform antimicrobial susceptibility tests on N gonorrhoeae, and many infections are documented by nonculture methods.
Clinical Findings

A. Symptoms and Signs

1. Asymptomatic gonorrhea—The ratio of asymptomatic to symptomatic gonorrhea infections in adolescents and adults is probably 3–4:1 in women and 0.5–1:1 in men. Asymptomatic infections are as infectious as symptomatic ones.

2. Uncomplicated genital gonorrhea

A. Male with urethritis—Urethral discharge is sometimes painful and bloody and may be white, yellow, or green. There may be associated dysuria. The patient usually is afebrile.

B. Prepubertal female with vaginitis—The only clinical findings initially may be dysuria and polymorphonuclear neutrophils in the urine. Vulvitis characterized by erythema, edema, and excoriation accompanied by a purulent discharge may follow.

C. Postpubertal female with cervicitis—Symptomatic disease is characterized by a purulent, foul-smelling vaginal discharge, dysuria, and occasionally dyspareunia. Fever and abdominal pain are absent. The cervix is frequently hyperemic and tender when touched. This tenderness is not worsened by moving the cervix, nor are the adnexa tender to palpation.

D. Rectal gonorrhea—Rectal gonorrhea often is asymptomatic. There may be purulent discharge, edema, and pain during evacuation.

3. Pharyngeal gonorrhea—Pharyngeal infection usually is asymptomatic. There may be some sore throat and, rarely, acute exudative tonsillitis with bilateral cervical lymphadenopathy and fever.

4. Conjunctivitis and iridocyclitis—Copious, usually purulent exudate is characteristic of gonococcal conjunctivitis. Newborns are symptomatic on days 2–4 of life. In the adolescent or adult, infection probably is spread from infected genital secretions by the fingers.

5. Pelvic inflammatory disease (salpingitis)—The interval between initiation of genital infection and its ascent to the uterine tubes is variable and may range from days to months. Menses frequently are the initiating factor. With the onset of a menstrual period, gonococci invade the endometrium, causing transient endometritis. Subsequently salpingitis may occur, resulting in pyosalpinx or hydrosalpinx. Rarely infection progresses to peritonitis or perihepatitis. Gonococcal salpingitis occurs in an acute, a subacute, or a chronic form. All three forms have in common tenderness on gentle movement of the cervix and bilateral tubal tenderness during pelvic examination.

Gonococci or Chlamydia trachomatis are the cause of about 50% of cases of pelvic inflammatory disease. A mixed infection caused by enteric bacilli, Bacteroides fragilis, or other anaerobes occur in the other 50%.

6. Gonococcal perihepatitis (Fitz-Hugh and Curtis syndrome)—In the typical clinical pattern, the patient presents with right upper quadrant tenderness in association with signs of acute or subacute salpingitis. Pain may be pleuritic and referred to the shoulder. Hepatic friction rub is a valuable but inconstant sign.

7. Disseminated gonorrhea—Dissemination follows asymptomatic more often than symptomatic genital infection and often results from gonococcal pharyngitis or anorectal gonorrhea. The most common form of disseminated gonorrhea is polyarthritis or polytenosynovitis, with or without dermatitis. Monoarticular arthritis is less common, and gonococcal endocarditis and meningitis are fortunately rare.

A. Polyarthritis—Disease usually begins with the simultaneous onset of low-grade fever, polyarthralgia, and malaise. After a day or so, joint symptoms become acute. Swelling, redness, and tenderness occur, frequently over the wrists, ankles, and knees but also in the fingers, feet, and other peripheral joints. Skin lesions may be noted at the same time. Discrete, tender, maculopapular lesions 5–8 mm in diameter appear that may become vesicular, pustular, and then hemorrhagic. They are few in number and noted on the fingers, palms, feet, and other distal surfaces and may be single or multiple. In patients with this form of the disease, blood cultures are often positive, but joint fluid rarely yields organisms. Skin lesions often are positive by Gram stain but rarely by culture. Genital, rectal, and pharyngeal cultures must be performed.

B. Monoarticular arthritis—In this somewhat less common form of disseminated gonorrhea, fever is often absent. Arthritis evolves in a single joint. Dermatitis usually does not occur. Systemic symptoms are minimal. Blood cultures are negative, but joint aspirates may yield gonococci on smear and culture. Genital, rectal, and pharyngeal cultures must be performed.

B. Laboratory Findings

Demonstration of gram-negative, kidney-shaped diplococci in smears of urethral exudate in males is presumptive evidence of gonorrhea. Positive culture confirms the diagnosis. Negative smears do not rule out gonorrhea. Gram-stained smears of cervical or vaginal discharge in girls are more difficult to interpret because of normal gram-negative flora, but they may be useful when technical personnel are experienced. In girls with suspected gonorrhea, both the cervical os and the anus should be cultured. Gonococcal pharyngitis requires culture for diagnosis.
Cultures for *N gonorrhoeae* are plated on a selective chocolate agar containing antibiotics (eg, Thayer-Martin agar) to suppress normal flora. If bacteriologic diagnosis is critical, suspected material should be cultured on chocolate agar as well. Because gonococci are labile, agar plates should be inoculated immediately and placed without delay in an atmosphere containing CO₂ (candle jar). When transport of specimens is necessary, material should be inoculated directly into Transgrow medium prior to shipment to an appropriate laboratory. In cases of possible sexual molestation, notify the laboratory that definite speciation is needed, because nongonococcal *Neisseria* species can grow on the selective media.

Nucleic acid amplification tests on urine or genital specimens now enable detection of *N gonorrhoeae* and *C trachomatis*. These tests have excellent sensitivity and are replacing culture in many laboratories. All children or adolescents with a suspected or established diagnosis of gonorrhea should have serologic tests for syphilis and HIV.

**Differential Diagnosis**

Urethritis in the male may be gonococcal or nongonococcal (NGU). NGU is a syndrome characterized by discharge (rarely painful), mild dysuria, and a subacute course. The discharge is usually scant or moderate in amount but may be profuse. *C trachomatis* is the only proven cause of NGU. Doxycycline (100 mg orally twice a day for 7 days) is efficacious. Single-dose azithromycin, 1 g orally, may achieve better compliance. *C trachomatis* has been shown to cause epididymitis in males and salpingitis in females.

Vulvovaginitis in a prepubertal female may be due to infection caused by miscellaneous bacteria, including *Shigella* and GAS, *Candida*, and herpes simplex. Discharges may be caused by trichomonads, *Enterobius vermicularis* (pin-worm), or foreign bodies. Symptom-free discharge (leukorrhea) normally accompanies rising estrogen levels.

Cervicitis in a postpubertal female, alone or in association with urethritis and involvement of Skene and Bartholin glands, may be due to infection caused by *Candida*, herpes simplex, *Trichomonas*, or discharge resulting from inflammation caused by foreign bodies (usually some form of contraceptive device). Leukorrhea may be associated with birth control pills.

Salpingitis may be due to infection with other organisms. The symptoms must be differentiated from those of appendicitis, urinary tract infection, ectopic pregnancy, endometriosis, or ovarian cysts or torsion.

Disseminated gonorrhea presents a differential diagnosis that includes meningococcemia, acute rheumatic fever, Henoch-Schönlein purpura, juvenile rheumatoid arthritis, lupus erythematosus, leptospirosis, secondary syphilis, certain viral infections (particularly rubella, but also enteroviruses and parvovirus), serum sickness, type B hepatitis (in the prodromal phase), infective endocarditis, and even acute leukemia and other types of cancer. The fully evolved skin lesions of disseminated gonorrhea are remarkably specific, and genital, rectal, or pharyngeal cultures, plus cultures of blood and joint fluid, usually yield gonococci from at least one source.

**Prevention**

Prevention of gonorrhea is principally a matter of sex education, condom use, and identification and treatment of contacts.

**Treatment**

**A. Uncomplicated Urethral, Endocervical, or Rectal Gonococcal Infections in Adolescents**

Ceftriaxone (250 mg intramuscularly in a single dose), and doxycycline (100 mg orally twice a day for 7 days), or azithromycin (1 g orally in a single dose) is recommended. Cefixime, cefotaxime, and cefotetan parenterally are alternative single-dose therapies. Fluoroquinolones are no longer recommended for therapy due to increasing rates of resistance. If ceftriaxone cannot be used, cefixime (400 mg orally in a single dose) and doxycycline (100 mg orally twice daily for 7 days) is recommended. Azithromycin (2 g orally once) can be used in the case of severe cephalosporin allergy. A repeated culture 7 days after therapy should be done if either oral regimen has been used.

Tetracyclines should be avoided in pregnancy, and repeated doses may stain the teeth of young children. Erythromycin or amoxicillin is recommended for therapy of *C trachomatis* in pregnant women; azithromycin is an alternative regimen. Repeat testing 3 weeks after completion of therapy is recommended in pregnant women.

Spectinomycin (2 g intramuscularly in a single dose) is used for penicillin- and cephalosporin-allergic patients, but is not currently available in the United States. A repeat culture after completion of therapy is not necessary in asymptomatic adolescents after the ceftriaxone–doxycycline regimen. A repeat culture after completion of therapy should be obtained from infants and children.

**B. Pharyngeal Gonococcal Infection**

Ceftriaxone (250 mg intramuscularly in a single dose) and azithromycin 1 g is a single dose or doxycycline 100 mg twice daily for 7 days should be used; neither spectinomycin nor amoxicillin is recommended.

**C. Disseminated Gonorrhea**

Recommended regimens include ceftriaxone (1 g intramuscularly or intravenously once daily) or cefotaxime (1 g intravenously every 8 hours or cefixime (1 g intravenously
every 8 hours). Oral therapy may follow parenteral therapy 24–48 hours after improvement. Recommended regimens include cefixime (400 mg) twice daily to complete 7 days of therapy. Fluoroquinolones are not recommended. If concurrent infection with Chlamydia is present or has not been excluded, a course of doxycycline, azithromycin, or erythromycin should also be prescribed.

D. Pelvic Inflammatory Disease

Doxycycline (100 mg twice a day orally) and either cefoxitin (2 g intramuscularly or intravenously every 6 hours) or cefotetan (2 g intramuscularly or intravenously every 12 hours) are given until the patient is clinically improved, then doxycycline is administered by mouth to complete 14 days of therapy. Clindamycin and gentamicin given intravenously until the patient improves clinically may be used rather than cefoxitin. Many other regimens have been used for therapy of pelvic inflammatory disease, although comparative efficacy data are limited.

E. Prepubertal Gonococcal Infections

1. Uncomplicated genitourinary, rectal, or pharyngeal infections—These infections may be treated with ceftriaxone (50 mg/kg/d to a maximum of 125 mg intramuscularly in a single dose). Children older than age 8 years should also receive doxycycline (100 mg orally twice daily for 7 days). The physician should evaluate all children for evidence of sexual abuse and coinfection with syphilis, Chlamydia, and HIV.

2. Disseminated gonorrhea—This should be treated with ceftriaxone (50 mg/kg once daily parenterally for 7 days).

BOTULISM

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Dry mucous membranes.
- Nausea and vomiting.
- Diplopia; dilated, unreactive pupils.
- Descending paralysis.

- Difficulty in swallowing and speech occurring within 12–36 hours after ingestion of toxin-contaminated food.
- Multiple cases in a family or group.
- Hypotonia and constipation in infants.
- Diagnosis by clinical findings and identification of toxin in blood, stool, or implicated food.

General Considerations

Botulism is a paralytic disease caused by Clostridium botulinum, an anaerobic, gram-positive, spore-forming bacillus normally found in soil. The organism produces an extremely potent neurotoxin. Of the seven types of toxin (A–G), types A, B, and E cause most human diseases. The toxin, a polypeptide, is so potent that 0.1 mg is lethal for humans.

Food-borne botulism usually results from ingestion of toxin-containing food. Preformed toxin is absorbed from the gut and produces paralysis by preventing acetylcholine release from cholinergic fibers at myoneural junctions. In the United States, home-canned vegetables are usually the cause. Commercially canned foods rarely are responsible. Virtually any food will support the growth of C botulinum spores into vegetative toxin-producing bacilli if an anaerobic, nonacid environment is provided. The food may not appear or taste spoiled. The toxin is heat-labile, but the spores are heat-resistant. Inadequate heating during processing (temperature < 115°C) allows the spores to survive and later resume toxin production. Boiling of foods for 10 minutes or heating at 80°C for 30 minutes before eating will destroy the toxin.

Infant botulism occurs in infants less than 12 months of age. The toxin appears to be produced by C botulinum organisms residing in the gastrointestinal tract. In some instances, honey has been the source of spores.

Annually, 10–15 cases of wound botulism are reported. Most cases occur in drug abusers with infection in intravenous or intramuscular injection sites.

Botulism, as a result of aerosolization of botulinum toxin, also could occur as the result of a bioterrorism event. Only three such cases of botulism have been reported; the incubation period was not well-defined, but was about 72 hours in the reported cases.

Prevention

Infant botulism is acquired by ingestion of botulism spores which then sporulate into C botulinum organisms that can form botulinum toxin. Honey can contain botulism spores so it is recommended that honey not be consumed by infants less than 12 months of age. Corn syrups that have not been pasteurized may pose a theoretical risk and some organizations (American Academy of Pediatrics) recommend that
Infants less than 12 months should not consume unpasteurized corn syrup.

Food-borne botulism is acquired by ingesting preformed botulism toxin in food. In the United States, food-borne botulism is most commonly seen with ingestion of home canned foods of low acidity (ie, corn, asparagus, green beans). However, baked potatoes wrapped in aluminum foil that have not been kept hot and home-fermented fish have also been associated with cases of botulism. Persons who eat home-canned foods should consider boiling foods for at least 10 minutes (can destroy potential toxin). Safe food handling practices include keeping foods either refrigerated (< 45°F) or hot (> 185°F), and disposing of any cracked jars or bulging/dented cans.

**Clinical Findings**

**A. Symptoms and Signs**

The incubation period for food-borne botulism is 8–36 hours. The initial symptoms are lethargy and headache. These are followed by double vision, dilated pupils, ptosis, and, within a few hours, difficulty with swallowing and speech. Pharyngeal paralysis occurs in some cases, and food may be regurgitated. The mucous membranes often are very dry. Descending skeletal muscle paralysis may be seen. Death usually results from respiratory failure.

Botulism patients present with a “classic triad”: (1) afebrile; (2) symmetrical, flaccid, descending paralysis with prominent bulbar palsies; and (3) clear sensorium. Recognition of this triad is important in making the clinical diagnosis. Botulism is caused by a toxin, thus there is no fever unless secondary infection (eg, aspiration pneumonia) occurs. Common bulbar palsies seen include dysphonia, dysphagia, dysarthria, and diplopia (four “Ds”).

Infant botulism is seen in infants younger than age 12 months (peak onset 2–8 months). Infants younger than age 2 weeks rarely develop botulism. The initial symptoms are usually constipation and progressive, often severe, hypotonia. Loss of facial expression, weak cry, and drooling are often noted. Clinical findings include constipation, weak suck and cry, pooled oral secretions, cranial nerve deficits, generalized weakness, and, on occasion, apnea. The characteristic electromyographic pattern of brief, small, abundant motor-unit action potentials (BSAPs) may help confirm the diagnosis.

**B. Laboratory Findings**

The diagnosis is made by demonstration of *C botulinum* toxin in stool, gastric aspirate or vomitus, or serum. Serum and stool samples can be sent for toxin confirmation (done by toxin neutralization mouse bioassay at CDC or state health departments). In infant botulism, serum assays for *C botulinum* toxin may be negative. These tests take time and therapy should not be withheld awaiting testing results. Foods that are suspected to be contaminated should be kept refrigerated and given to public health personnel for testing. Laboratory findings, including CSF examination, are usually normal. Electromyography suggests the diagnosis if the characteristic brief, small abundant motor-unit action potentials (BSAP) abnormalities are seen. A nondiagnostic electromyogram does not exclude the diagnosis.

**Differential Diagnosis**

Guillain-Barré syndrome is characterized by ascending paralysis, sensory deficits, and elevated CSF protein without pleocytosis.

Other illnesses that should be considered include poliomyelitis, post diphtheritic polyneuritis, certain chemical intoxications, tick paralysis, and myasthenia gravis. The history and elevated CSF protein characterize postdiphtheritic polyneuritis. Tick paralysis presents with a flaccid ascending motor paralysis. An attached tick should be sought. Myasthenia gravis usually occurs in adolescent girls. It is characterized by ocular and bulbar symptoms, normal pupils, fluctuating weakness, absence of other neurologic signs, and clinical response to cholinesterase inhibitors.

**Complications**

Difficulty in swallowing leads to aspiration pneumonia. Serious respiratory paralysis may be fatal despite assisted ventilation and intensive supportive measures.

**Treatment**

**A. Specific Measures**

Patients with suspected botulism should be hospitalized and monitored closely for signs of impending respiratory failure and inability to manage secretions. Early treatment of botulism with antitoxin (food-borne or wound botulism) or passive human botulism immune globulin (infant botulism) is beneficial. Treatment should begin as soon as the clinical diagnosis is made (prior to microbiologic or toxin confirmation). Contact your State Health Department’s emergency 24-hour telephone number immediately when a case of botulism is suspected to assist in therapeutic decisions and to help obtain treatment product.

For suspected wound or food-borne botulism (noninfant botulism), patients should be treated with the heptavalent botulinum antitoxin (HBAT), which is only available from the CDC under an investigational new drug protocol. HBAT is an equine derived antitoxin and contains antibodies to all seven known botulinum toxin types (A through G). The treatment protocol (available from the CDC) includes detailed instructions for intravenous administration.
of antitoxin. State Health Departments can assist practitioners in obtaining the antitoxin; if State Health Department officials are unavailable, the CDC (770-488-7100) can be contacted for help in obtaining the product and for consultation. In addition, epidemic assistance, and laboratory testing services are available from the CDC through state health departments.

For treatment of infant botulism, intravenous human botulism immune globulin (Baby-BIG) is approved by the U.S. Food and Drug Administration (FDA) for use. Baby-BIG is a product containing high titers of neutralizing antibodies against type A and B toxin and is made from pooled plasma of adults who were immunized with a botulism toxoid vaccine. Results of a placebo-controlled clinical trial of use in infant botulism showed reduction in the mean hospital stay (2.5 weeks in treated patients vs 5.5 weeks in the placebo group) and decrease in mechanical ventilation time in the Baby-BIG–treated group. Although the cost of the preparation is very high, it still is cost-saving since there is a substantial reduction in hospital days, intensive care unit stay, and ventilator time in treated infants. Baby-BIG is not indicated for use in any form of botulism (wound, food-borne) other than infant botulism. To obtain Baby-BIG (in any state), contact the Infant Botulism Treatment and Prevention Program at: (510) 231-7600.

B. General Measures

General and supportive therapy consists of bed rest, ventilatory support (if necessary), fluid therapy, and enteral or parenteral nutrition. Aminoglycoside antimicrobials and clindamycin may exacerbate neuromuscular blockage and should be avoided.

Prognosis

The mortality rate has declined substantially in recent years and currently is at 6%. In nonfatal cases, symptoms subside over 2–3 months and recovery is usually complete.

Centers for Disease Control and Prevention (CDC): Investigational heptavalent botulinum antitoxin (HBAT) to replace licensed botulinum antitoxin AB and investigational botulinum antitoxin E. MMWR 2010;59(10):299 [PMID: 20300057].

TETANUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Nonimmunized or partially immunized patient.
- History of skin wound.
- Spasms of jaw muscles (trismus).
- Stiffness of neck, back, and abdominal muscles, with hyperirritability and hyperreflexia.
- Episodic, generalized muscle contractions.
- Diagnosis is based on clinical findings and the immunization history.

General Considerations

Tetanus is caused by Clostridium tetani, an anaerobic, gram-positive bacillus that produces a potent neurotoxin. In unimmunized or incompletely immunized individuals, infection follows contamination of a wound by soil containing Clostridial spores from animal manure. The toxin reaches the CNS by retrograde axon transport, is bound to cerebral gangliosides, and appears to increase reflex excitability in neurons of the spinal cord by blocking function of inhibitory synapses. Intense muscle spasms result. Two-thirds of cases in the United States follow minor puncture wounds of the hands or feet. In many cases, no history of a wound can be obtained. Injecting substances and drug abuse may be risk factors (in individuals who are not tetanus-immune). In the newborn, usually in underdeveloped countries, infection generally results from contamination of the umbilical cord. The incubation period typically is 4–14 days but may be longer. In the United States, cases in young children are due to failure to immunize. Eighty-five percent of cases occur in adults older than 25 years.

Prevention

A. Tetanus Toxoid

Active immunization with tetanus toxoid prevents tetanus. Immunity is almost always achieved after the third dose of vaccine. Tetanus immune globulin (TIG) is an additional agent used to prevent tetanus in persons who have received less than three doses of tetanus toxoid or in immunocompromised patients who do not make sufficient antibody (ie, HIV infection; see Chapter 10). A tetanus toxoid booster at the time of injury is needed if none has been given in the past 10 years—or within 5 years for heavily contaminated wounds. Nearly all cases of tetanus (99%) in the United States are in nonimmunized or incompletely immunized individuals.
individuals. Many adolescents and adults lack protective antibody.

**B. Wound Care and Prophylaxis for Tetanus-Prone Wounds**

Wounds that are contaminated with soil, debris, feces, or saliva are at increased risk for tetanus. Puncture wounds or wounds that contain devitalized tissue are at increased risk of infection with *C. tetani*. This includes wounds that result from crush injury, frostbite, burns, or avulsion. All wounds should be adequately cleaned, foreign material removed, and debrided if necrotic or devitalized tissue is present or if residual foreign matter is present. The decision to use tetanus toxoid-containing vaccine or human TIG depends on the type of injury and the tetanus immunization status of the patient (see Chapter 10; Table 10–5). TIG should be used in children with fewer than three previous tetanus toxoid immunizations (DPT, DPaT, DT, Td, Tdap) who have tetanus-prone wounds, and should be administered to HIV-infected children with tetanus-prone wounds, regardless of their immunization history. When TIG is indicated for wound, prophylaxis 250 units are given intramuscularly regardless of age. If tetanus immunization is incomplete, a dose of age-appropriate vaccine should be given. When both are indicated, tetanus toxoid and TIG should be administered concurrently at different sites using different syringes (see Chapter 10).

Prophylactic antimicrobials are useful if the child is unimmunized and TIG is not available.

**Clinical Findings**

**A. Symptoms and Signs**

The first symptom often is mild pain at the site of the wound, followed by hypertonicity and spasm of the regional muscles. Characteristically, difficulty in opening the mouth (trismus) is evident within 48 hours. In newborns, the first signs are irritability and inability to nurse. The infant may then develop stiffness of the jaw and neck, increasing dysphagia, and generalized hyperreflexia with rigidity and spasms of all muscles of the abdomen and back (opisthotonos). The facial distortion resembles a grimace (risus sardonicus). Difficulty in swallowing and convulsions triggered by minimal stimuli such as sound, light, or movement may occur. Individual spasms may last seconds or minutes. Recurrent spasms are seen several times each hour, or they may be almost continuous. In most cases, the temperature is normal or only mildly elevated. A high or subnormal temperature is a bad prognostic sign. Patients are fully conscious and lucid. A profound circulatory disturbance associated with sympathetic overactivity may occur on the second to fourth day, which may contribute to the mortality rate. This is characterized by elevated blood pressure, increased cardiac output, tachycardia (> 20 beats/min), and arrhythmia.

**B. Laboratory Findings**

The diagnosis is made on clinical grounds. There may be a mild polymorphonuclear leukocytosis. The CSF is normal with the exception of mild elevation of opening pressure. Serum muscle enzymes may be elevated. Transient electrocardiographic and electroencephalographic abnormalities may occur. Anaerobic culture and microscopic examination of pus from the wound can be helpful, but *C. tetani* is difficult to grow, and the drumstick-shaped gram-positive bacilli often cannot be found.

**Differential Diagnosis**

Poliomyelitis is characterized by asymmetrical paralysis in an incompletely immunized child. The history of an animal bite and the absence of trismus may suggest rabies. Local infections of the throat and jaw should be easily recognized. Bacterial meningitis, phenothiazine reactions, decerebrate posturing, narcotic withdrawal, spondylitis, and hypocalcemic tetany may be confused with tetanus.

**Complications**

Complications include sepsis, malnutrition, pneumonia, atelectasis, asphyxial spasms, decubitus ulcers, and fractures of the spine due to intense contractions. They can be prevented in part by skilled supportive care.

**Treatment**

**A. Specific Measures**

Human TIG in a single dose of 3000–6000 units, intramuscularly, is given to children and adults. Doses of 500 units have been used in infants. Infiltration of part of the TIG dose around the wound is recommended. If TIG is indicated, but not available, intravenous immune globulin in a dose of 200–400 mg/kg intravenously can be used (although it is not licensed for this indication). In countries where TIG or immune globulin are not available, equine tetanus antitoxin may be available. Surgical debridement of wounds is indicated, but more extensive surgery or amputation to eliminate the site of infection is not necessary. Antibiotics are given to attempt to decrease the number of vegetative forms of the bacteria to decrease toxin production: oral or intravenous metronidazole (30 mg/kg/d in four divided doses; maximum 4 g/d) for 10–14 days is the preferred agent.

**B. General Measures**

The patient is kept in a quiet room with minimal stimulation. Control of spasms and prevention of hypoxic episodes are crucial. Benzodiazepines can be used to help control spasms and provide some sedation. Mechanical ventilation and muscle paralysis are necessary in severe cases. Nasogastric
or intravenous feedings should be used to limit stimulation of feedings and prevent aspiration.

**Prognosis**

The fatality rate in newborns and heroin-addicted individuals is high. The overall mortality rate in the United States is 11%. The fatality rate depends on the quality of supportive care, the patient’s age, and the patient’s vaccination history. Many deaths are due to pneumonia or respiratory failure. If the patient survives 1 week, recovery is likely.

**GAS GANGRENE**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Contamination of a wound with soil or feces.
- Massive edema, skin discoloration, bleb formation, and pain in an area of trauma.
- Serosanguineous exudate from wound.
- Crepitation of subcutaneous tissue.
- Rapid progression of signs and symptoms.
- Clostridia cultured or seen on stained smears.

**General Considerations**

Gas gangrene (Clostridial myonecrosis) is a necrotizing infection that follows trauma or surgery and is caused by several anaerobic, gram-positive, spore-forming bacilli of the genus Clostridium. Occasionally the source is the gastrointestinal tract and muscles are hematogenously seeded. The spores are found in soil, feces, and vaginal secretions. In devitalized tissue, the spores germinate into vegetative bacilli that proliferate and produce toxins, causing thrombosis, hemolysis, and tissue necrosis. C. perfringens, the species causing approximately 80% of cases of gas gangrene, produces at least eight such toxins. The areas involved most often are the extremities, abdomen, and uterus. Clostridium septicum may also cause myonecrosis and causes septicemia in patients with neutropenia. Nonclostridial infections with gas formation can mimic clostridial infections and are more common. Neutropenia is a risk factor for this severe infection.

**Prevention**

Gas gangrene can be prevented by the adequate cleansing and debridement of all wounds. It is essential that foreign bodies and dead tissue be removed. A clean wound does not provide a suitable anaerobic environment for the growth of Clostridial species.

**Clinical Findings**

**A. Symptoms and Signs**

The onset of gas gangrene usually is sudden, often 1 day after trauma or surgery (mean, 3–4 days), but can be delayed up to 20 days. The skin around the wound becomes discolored (pale, red, or purple), with hemorrhagic bullae, serosanguineous exudate, and crepitus may be observed the subcutaneous tissues. The absence of crepitus does not rule out the diagnosis. Pain and swelling usually are intense. Systemic illness appears early and progresses rapidly to intravascular hemolysis, jaundice, shock, toxic delirium, and renal failure.

**B. Laboratory Findings**

Isolation of the organism requires anaerobic culture. Gram-stained smears may demonstrate many gram-positive rods and few inflammatory cells.

**C. Imaging**

Radiographs may demonstrate gas in tissues, but this is a late finding and is also seen in infections with other gas-forming organisms or may be due to air introduced into tissues during trauma or surgery.

**D. Operative Findings**

Direct visualization of the muscle at surgery may be necessary to diagnose gas gangrene. Early, the muscle is pale and edematous and does not contract normally; later, the muscle may be frankly gangrenous.

**Differential Diagnosis**

Gangrene and cellulitis caused by other organisms and Clostridial cellulitis (not myonecrosis) must be distinguished. Necrotizing fasciitis may resemble gas gangrene.

**Treatment**

**A. Specific Measures**

Penicillin G (300,000–400,000 U/kg/d intravenously in six divided doses) should be given, combined with clindamycin or metronidazole. Clindamycin, metronidazole, meropenem,
and imipenem/cilastatin are alternatives for penicillin-allergic patients. Some experts recommend a combination of penicillin and clindamycin. Clindamycin is a protein synthesis inhibitor and may inhibit toxin production.

**B. Surgical Measures**

Surgery should be prompt and extensive, with removal of all necrotic tissue. Compartment syndromes can occur even if there are few cutaneous findings. Checking compartment pressures in patients with severe pain and any signs of compartment syndrome is prudent.

**C. Hyperbaric Oxygen**

Hyperbaric oxygen therapy is controversial but good outcomes have been reported in nonrandomized studies using hyperbaric oxygen in combination with surgery and antibiotics.

**Prognosis**

Clostridial myonecrosis is fatal if untreated. With early diagnosis, antibiotics, and surgery, the mortality rate is 20%–60%. Involvement of the abdominal wall, leukopenia, intravascular hemolysis, renal failure, and shock are ominous prognostic signs.

**DIPHTHERIA**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Gray, adherent pseudomembrane, most often in the pharynx but also in the nasopharynx or trachea.
- Sore throat, serosanguinous nasal discharge, hoarseness, and fever in a nonimmunized child.
- Peripheral neuritis or myocarditis.
- Positive culture.
- Treatment should not be withheld pending culture results.

**Clinical Findings**

**A. Symptoms and Signs**

1. **Pharyngeal diphtheria**—Early manifestations of diphtheritic pharyngitis are mild sore throat, moderate fever, and malaise, followed fairly rapidly by prostration and circulatory collapse. The pulse is more rapid than the fever would seem to justify. A pharyngeal membrane forms and may spread into the nasopharynx or the trachea, producing respiratory obstruction. The membrane is tenacious and gray and is surrounded by a narrow zone of erythema and a broader zone of edema. The cervical lymph nodes become swollen, and swelling is associated with brawny edema of the neck (so-called bull neck). Laryngeal diphtheria presents with stridor, which can progress to obstruction of the airway.

2. **Other forms**—Cutaneous, vaginal, and wound diphtheria account for up to one-third of cases and are characterized by ulcerative lesions with membrane formation.
B. Laboratory Findings

Diagnosis is clinical. Direct smears are unreliable. Material is obtained from the nose, throat, or skin lesions, if present, for culture, but specialized culture media are required. Between 16 and 48 hours is required before identification of the organism. A toxigenicity test is then performed. Cultures may be negative in individuals who have received antibiotics. The WBC count usually is normal, but hemolytic anemia and thrombocytopenia are frequent.

Differential Diagnosis

Pharyngeal diphtheria resembles pharyngitis secondary to β-hemolytic streptococcus, Epstein-Barr virus, or other viral respiratory pathogens. A nasal foreign body or purulent sinusitis may mimic nasal diphtheria. Other causes of laryngeal obstruction include epiglottitis and viral croup. Guillain-Barré syndrome, poliomyelitis, or acute poisoning may mimic the neuropathy of diphtheria.

Complications

A. Myocarditis

Diphtheritic myocarditis is characterized by a rapid, thready pulse; indistinct heart sounds, ST-T wave changes, conduction abnormalities, dysrhythmias, or cardiac failure; hepatomegaly; and fluid retention. Myocardial dysfunction may occur from 2 to 40 days after the onset of pharyngitis.

B. Polyneuritis

Neuritis of the palatal and pharyngeal nerves occurs during the first or second week. Nasal speech and regurgitation of food through the nose are seen. Diplopia and strabismus occur during the third week or later. Neuritis may also involve peripheral nerves supplying the intercostal muscles, diaphragm, and other muscle groups. Generalized paresis usually occurs after the fourth week.

C. Bronchopneumonia

Secondary pneumonia is common in fatal cases.

Prevention

A. Immunization

Immunization with diphtheria toxoid combined with pertussis and tetanus toxoids (DTaP) should be used routinely for infants and children (see Chapter 10).

B. Care of Exposed Susceptibles

Children exposed to diphtheria should be examined, and nose and throat cultures obtained. If signs and symptoms of early diphtheria are found, antibiotic treatment should be instituted. Immunized asymptomatic individuals should receive diphtheria toxoid if a booster has not been received within 5 years. Unimmunized close contacts should receive either erythromycin orally (40 mg/kg/d in four divided doses) for 7 days or benzathine penicillin G intramuscularly (25,000 U/kg), active immunization with diphtheria toxoid, and observation daily.

Treatment

A. Specific Measures

1. Antitoxin—To be effective, diphtheria antitoxin should be administered within 48 hours (see Chapter 9).

2. Antibiotics—Penicillin G (150,000 U/kg/d intravenously or intramuscularly) should be given for 14 days. For penicillin-allergic patients, erythromycin (40 mg/kg/d) is given orally for 14 days.

B. General Measures

Bed rest in the hospital for 10–14 days is usually required. All patients must be strictly isolated for 1–7 days until respiratory secretions are noncontagious. Isolation may be discontinued when two successive nose and throat cultures at 24-hour intervals are negative. These cultures should not be taken until at least 24 hours have elapsed since the cessation of antibiotic treatment.

C. Treatment of Carriers

All carriers should receive treatment. Erythromycin (40 mg/kg/d orally in three or four divided doses), penicillin V potassium (50 mg/kg/d) for 10 days, or benzathine penicillin G (600,000–1,200,000 units intramuscularly) should be given. All carriers must be quarantined. Before they can be released, carriers must have two negative cultures of both the nose and the throat taken 24 hours apart and obtained at least 24 hours after the cessation of antibiotic therapy.

Prognosis

Mortality varies from 3% to 25% and is particularly high in the presence of early myocarditis. Neuritis is reversible; it is fatal only if an intact airway and adequate respiration cannot be maintained. Permanent heart damage from myocarditis occurs rarely.

Centers for Disease Control and Prevention (CDC): Diphtheria. Available at: http://www.cdc.gov/ncidod/dbmd/diseaseinfo/diphtheria_t.htm
INFECTIONS DUE TO ENTEROBACTERIACEAE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Diarrhea by several different mechanisms due to *E coli*.
- Hemorrhagic colitis and hemolytic-uremic syndrome.
- Neonatal sepsis or meningitis.
- Urinary tract infection.
- Opportunistic infections.
- Diagnosis confirmed by culture.

**General Considerations**

Enterobacteriaceae are a family of gram-negative bacilli that are normal flora in the gastrointestinal tract and are also found in water and soil. They cause gastroenteritis, urinary tract infections, neonatal sepsis and meningitis, and opportunistic infections. *E coli* is the organism in this family that most commonly causes infection in children, but *Klebsiella, Morganella, Enterobacter, Serratia, Proteus*, and other genera are also important, particularly in the compromised host. *Shigella* and *Salmonella* are discussed in separate sections.

*E coli* strains capable of causing diarrhea were originally termed enteropathogenic *E coli* (EPEC) and were recognized by serotype. It is now known that *E coli* may cause diarrhea by several distinct mechanisms. Classic EPEC strains cause a characteristic histologic injury in the small bowel termed adherence and effacement. Enterotoxigenic *E coli* (ETEC) causes a secretory, watery diarrhea. ETEC adheres to enterocytes and secretes one or more plasmid-encoded enterotoxins. One of these, heat-labile toxin, resembles cholera toxin in structure, function, and mechanism of action. Enteroinvasive *E coli* (EIEC) are very similar to *Shigella* in their pathogenetic mechanisms. Shigella-toxin producing *E coli* (STEC) cause hemorrhagic colitis and the hemolytic-uremic syndrome. The most common STEC serotype is O157:H7, although several other serotypes cause the same syndrome. These strains elaborate one of several cytotoxins, closely related to Shiga toxin produced by *Shigella dysenteriae*. Outbreaks of hemolytic-uremic syndrome associated with STEC have followed consumption of inadequately cooked ground beef. Thorough heating to 68–71°C is necessary. Unpasteurized fruit juice, various uncooked vegetables, and contaminated water also have caused infections and epidemics. The common source for STEC in all of these foods and water is the feces of cattle. Person-to-person spread including spread in day care centers by the fecal-oral route has been reported. Over 5400 cases of STEC were reported in the United States in 2010.

*E coli* that aggregate on the surface of hep cells in tissue culture are termed enteroaggregative *E coli* (EAggEC). EAggEC causes diarrhea by a distinct but unknown mechanism.

Eighty percent of *E coli* strains causing neonatal meningitis possess specific capsular polysaccharide (K1 antigen), which, alone or in association with specific somatic antigens, confers virulence. Approximately 90% of urinary tract infections in children are caused by *E coli*. *E coli* binds to the uroepithelium by P-fimbriae, which are present in more than 90% of *E coli* that cause pyelonephritis. Other bacterial cell surface structures, such as O and K antigens, and host factors are also important in the pathogenesis of urinary tract infections.

*Klebsiella, Enterobacter, Serratia*, and *Morganella* are normally found in the gastrointestinal tract and in soil and water. *Klebsiella* may cause a bronchopneumonia with cavity formation. *Klebsiella, Enterobacter*, and *Serratia* are often hospital-acquired opportunists associated with antibiotic usage, debilitated states, and chronic respiratory conditions. They frequently cause urinary tract infection or sepsis. Many of these infections are difficult to treat because of antibiotic resistance. Antibiotic susceptibility tests are necessary. Parenteral third-generation cephalosporins are usually more active than ampicillin, but resistance due to high-level production of chromosomal cephalosporinase may occur. *Enterobacter* and *Serratia* strains broadly resistant to cephalosporins also cause infections in hospitalized newborns and children. Aminoglycoside antibiotics are usually effective but require monitoring of serum levels to ensure therapeutic and nontoxic levels. Carbapenem-resistant Enterobacteriaceae are a serious concern due to limited options for therapy.

**Clinical Findings**

**A. Symptoms and Signs**

1. *E coli* gastroenteritis—*E coli* may cause diarrhea of varying types and severity. ETEC usually produce mild, self-limiting illness without significant fever or systemic toxicity, often known as traveler’s diarrhea. However, diarrhea may be severe in newborns and infants, and occasionally an older child or adult will have a cholera-like syndrome. EIEC strains cause a shigellosis-like illness, characterized by fever, systemic symptoms, blood and mucus in the stool, and leukocytosis, but currently are uncommon in the United States. STEC strains cause hemorrhagic colitis. Diarrhea initially is watery and fever usually is absent. Abdominal pain and cramping occur; diarrhea progresses to blood streaking or grossly bloody stools. Hemolytic-uremic syndrome occurs within a few days of diarrhea in 2%–5% of children and is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and renal failure (see Chapter 24).
2. Neonatal sepsis—Findings include jaundice, hepatosplenomegaly, fever, temperature lability, apneic spells, irritability, and poor feeding. Respiratory distress develops when pneumonia occurs; it may appear indistinguishable from respiratory distress syndrome in preterm infants. Meningitis is associated with sepsis in 25%–40% of cases. Other metastatic foci of infection may be present, including pneumonia and pyelonephritis. Sepsis may lead to severe metabolic acidosis, shock, DIC, and death.

3. Neonatal meningitis—Findings include high fever, full fontanelles, vomiting, coma, convulsions, paralyses, poor or absent Moro reflex, opisthotonos, and occasionally hypertonia or hypotonia. Sepsis coexists or precedes meningitis in most cases. Thus, signs of sepsis often accompany those of meningitis. CSF usually shows a cell count of over 1000/μL, mostly polymorphonuclear neutrophils, and bacteria on Gram stain. CSF glucose concentration is low (usually less than half that of blood), and the protein is elevated above the levels normally seen in newborns and premature infants (> 150 mg/dL).

4. Acute urinary tract infection—Symptoms include dysuria, increased urinary frequency, and fever in the older child. Nonspecific symptoms such as anorexia, vomiting, irritability, failure to thrive, and unexplained fever are seen in children younger than age 2 years. Young infants may present with jaundice. As many as 1% of school-aged girls and 0.05% of boys have asymptomatic bacteriuria. Screening for and treatment of asymptomatic bacteriuria is not recommended.

B. Laboratory Findings

Because E coli are normal flora in the stool, a positive stool culture alone does not prove that the E coli in the stool are causing disease. Serotyping, tests for enterotoxin production or invasiveness, and tests for P-fimbriae are performed in research laboratories. MacConkey agar with sorbitol substituted for lactose (SMAC agar) is useful to screen stool for STEC. Serotyping and testing for enterotoxin are available at many state health departments and increasingly from commercial and hospital laboratories. Blood cultures are positive in neonatal sepsis. Cultures of CSF and urine should also be obtained. The diagnosis of urinary tract infections is discussed in Chapter 24.

Differential Diagnosis

The clinical picture of EPEC infection may resemble that of salmonellosis, shigellosis, or viral gastroenteritis. Neonatal sepsis and meningitis caused by E coli can be differentiated from other causes of neonatal infection only by blood and CSF culture.

Treatment

A. Specific Measures

1. E coli gastroenteritis—Gastroenteritis due to EPEC seldom requires antimicrobial treatment. Fluid and electrolyte therapy, preferably given orally, may be required to avoid dehydration. Bismuth subsalicylate reduces stool volume by about one-third in infants with watery diarrhea, probably including ETEC. In nursery outbreaks, E coli gastroenteritis has been treated with neomycin (100 mg/kg/d orally in three divided doses for 5 days). Clinical efficacy is not established. Traveler’s diarrhea may be treated with azithromycin in children and with fluoroquinolones in adults, although resistance to these drugs is increasing. The risk of hemolytic-uremic syndrome is not proven to be increased by antimicrobial therapy of EHEC cases, but most experts recommend no treatment of suspected cases.

2. E coli sepsis and pneumonia—The drugs of choice are ampicillin (150–200 mg/kg/d, given intravenously or intramuscularly in divided doses every 4–6 hours), cefotaxime (150–200 mg/kg/d, given intravenously or intramuscularly in divided doses every 6–8 hours), ceftriaxone (50–100 mg/kg/d, given intramuscularly as single dose or in two divided doses), and gentamicin (5.0–7.5 mg/kg/d, given intramuscularly or intravenously in divided doses every 8 hours). Initial therapy often includes at least two drugs until microbial etiology is established and susceptibility testing is completed. Treatment is continued for 10–14 days. Amikacin or tobramycin may be used instead of gentamicin if the strain is susceptible. Third-generation cephalosporins are often an attractive alternative as single-drug therapy and do not require monitoring for toxicity.

3. E coli meningitis—Third-generation cephalosporins such as cefotaxime (200 mg/kg/d intravenously in four divided doses) are given for a minimum of 3 weeks. Ampicillin (200–300 mg/kg/d intravenously in four to six divided doses) and gentamicin (5.0–7.5 mg/kg/d intramuscularly or intravenously in three divided doses) also are effective for susceptible strains. Treatment with intrathecal and intraventricular aminoglycosides does not improve outcome. Serum levels need to be monitored.

4. Acute urinary tract infection—(See Chapter 24.)

Prognosis

Death due to gastroenteritis leading to dehydration can be prevented by early fluid and electrolyte therapy. Neonatal sepsis with meningitis is still associated with a mortality rate of over 50%. Most children with recurrent urinary tract infections do well if they have no underlying anatomic defects. The mortality rate in opportunistic infections usually depends on the severity of infection and the underlying condition.
PSEUDOMONAS INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Opportunistic infection.
- Confirmed by cultures.

General Considerations

Pseudomonas aeruginosa is an aerobic gram-negative rod with versatile metabolic requirements. The organism may grow in distilled water and in commonly used disinfectants, complicating infection control in medical facilities. P aeruginosa is both invasive and destructive to tissue as well as toxigenic due to secreted exotoxins, all factors that contribute to virulence. Other genera previously classified as Pseudomonas frequently cause nosocomial infections and infections in immunocompromised children. Stenotrophomonas maltophilia (previously Pseudomonas maltophilia) and Burkholderia cepacia (previously Pseudomonas cepacia) are the most frequent.

P aeruginosa is an important cause of infection in children with cystic fibrosis, neoplastic disease, neutropenia, or extensive burns and in those receiving antibiotic therapy. Infections of the urinary and respiratory tracts, ears, mastoids, paranasal sinuses, eyes, skin, meninges, and bones are seen.

Pseudomonas pneumonia is a common nosocomial infection in patients receiving assisted ventilation.

P aeruginosa sepsis may be accompanied by characteristic peripheral lesions called ecthyma gangrenosum. Ecthyma gangrenosum also may occur by direct invasion through intact skin in the groin, axilla, or other skinfolds. P aeruginosa is an infrequent cause of sepsis in previously healthy infants and may be the initial sign of underlying medical problems. P aeruginosa osteomyelitis often complicates puncture wounds of the feet. P aeruginosa is a frequent cause of malignant external otitis media and of chronic suppurative otitis media. Outbreaks of vesiculopustular skin rash have been associated with exposure to contaminated water in whirlpool baths and hot tubs.

P aeruginosa infects the tracheobronchial tree of nearly all patients with cystic fibrosis. Mucoid exopolysaccharide, an exuberant capsule, is characteristically overproduced by isolates from patients with cystic fibrosis. Although bacteremia seldom occurs, patients with cystic fibrosis ultimately succumb to chronic lung infection with P aeruginosa. Infection due to B cepacia has caused a rapidly progressive pulmonary disease in some colonized patients and may be spread by close contact.

Osteomyelitis of the calcaneus or other foot bones occurs after punctures such as stepping on a nail and is commonly due to P aeruginosa.

Clinical Findings

The clinical findings depend on the site of infection and the patient’s underlying disease. Sepsis with these organisms resembles gram-negative sepsis with other organisms, although the presence of ecthyma gangrenosum suggests the diagnosis. The diagnosis is made by culture. Pseudomonas infection should be suspected in neonates and neutropenic patients with clinical sepsis. A severe necrotizing pneumonia occurs in patients on ventilators.

Patients with cystic fibrosis have a persistent bronchitis that progresses to bronchiectasis and ultimately to respiratory failure. During exacerbations of illness, cough and sputum production increase with low-grade fever, malaise, and diminished energy.

The purulent aural drainage without fever in patients with chronic suppurative otitis media is not distinguishable from that due to other causes.

Prevention

A. Infections in Debilitated Patients

Colonization of extensive second- and third-degree burns by P aeruginosa can lead to fatal septicemia. Aggressive debridement and topical treatment with 0.5% silver nitrate solution, 10% mafenide cream, or silver sulfadiazine will greatly inhibit P aeruginosa contamination of burns.
(See Chapter 12 for a discussion of burn wound infections and prevention.)

B. Nosocomial Infections

Faucet aerators, communal soap dispensers, disinfectants, improperly cleaned inhalation therapy equipment, infant incubators, and many other sources that usually are associated with wet or humid conditions all have been associated with Pseudomonas epidemics. Infant-to-infant transmission by nursery personnel carrying Pseudomonas on the hands is frequent in neonatal units. Careful maintenance of equipment and enforcement of infection control procedures are essential to minimize nosocomial transmission.

C. Patients with Cystic Fibrosis

Chronic infection of the lower respiratory tract occurs in nearly all patients with cystic fibrosis. The infecting organism is seldom cleared from the respiratory tract, even with intensive antimicrobial therapy, and the resultant injury to the lung eventually leads to pulmonary insufficiency. Treatment is aimed at controlling signs and symptoms of the infection.

Treatment

Pseudomonas aeruginosa is inherently resistant to many antimicrobials and may develop resistance during therapy. Mortality rates in hospitalized patients exceed 50%, owing both to the severity of underlying illnesses in patients predisposed to Pseudomonas infection and to the limitations of therapy. Antibiotics effective against Pseudomonas include the aminoglycosides, ureidopenicillins (ticarcillin and piperacillin), β-lactamase inhibitor with a ureidopenicillin (ticarcillin-clavulanate and piperacillin-tazobactam), expanded-spectrum cephalosporins (cefazidime and cefepime), imipenem, meropenem, and ciprofloxacin. Colistin has been used in some children with multidrug resistance. Antimicrobial susceptibility patterns vary from area to area, and resistance tends to appear as new drugs become popular. Treatment of infections is best guided by clinical response and susceptibility tests.

Gentamicin or tobramycin (5.0–7.5 mg/kg/d, given intramuscularly or intravenously in three divided doses) or amikacin (15–22 mg/kg/d, given in two or three divided doses) in combination with ticarcillin (200–300 mg/kg/d, given intravenously in four to six divided doses) or with another antipseudomonal β-lactam antibiotic is recommended for treatment of serious Pseudomonas infections. Cefazidime (150–200 mg/kg/d, given in four divided doses) or cefepime (150 mg/kg/d, given in three divided doses) has excellent activity against Pseudomonas aeruginosa. Treatment should be continued for 10–14 days. Treatment with two active drugs is recommended for all serious infections.

Pseudomonas osteomyelitis due to punctures requires thorough surgical debridement and antimicrobial therapy for 2 weeks. Pseudomonas folliculitis does not require antibiotic therapy.

Oral or intravenous ciprofloxacin is also effective against susceptible Pseudomonas aeruginosa, but is not approved by the FDA for use in children except in the case of urinary tract infection. Nonetheless, in some circumstances of antimicrobial resistance, or when the benefits clearly outweigh the small risks, ciprofloxacin may be used.

Chronic suppurative otitis media responds to intravenous ceftazidime (150–200 mg/kg/d in three or four divided doses) given until the drainage has ceased for 3 days. Twice-daily ceftazidime with aural debridement and cleaning given on an outpatient basis has also been successful. Swimmer’s ear may be caused by Pseudomonas aeruginosa and responds well to topical drying agents (alcohol–vinegar mix) and cleansing.

Prognosis

Because debilitated patients are most frequently affected, the mortality rate is high. These infections may have a protracted course, and eradication of the organisms may be difficult.

SALMONELLA GASTROENTERITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Nausea, vomiting, headache, meningoismus.

Fever, diarrhea, abdominal pain.

Culture or organism from stool, blood, or other specimens.

General Considerations

Salmonellae are gram-negative rods that frequently cause food-borne gastroenteritis and occasionally bacteremic infection of bone, meninges, and other foci. Approximately
2400 serotypes of \textit{Salmonella enterica} are recognized. \textit{Salmonella typhimurium} is the most frequently isolated serotype in most parts of the world. Although 54,000 cases were reported in 2010, it is estimated that 100 or more occur for each one reported. This yields an estimate or more than 5 million cases yearly in the United States.

Salmonellae are able to penetrate the mucin layer of the small bowel and attach to epithelial cells. Organisms penetrate the epithelial cells and multiply in the submucosa. Infection results in fever, vomiting, and watery diarrhea; the diarrhea occasionally includes mucus and polymorphonuclear neutrophils in the stool. Although the small intestine is generally regarded as the principal site of infection, colitis also occurs. \textit{S. typhimurium} frequently involves the large bowel.

\textit{Salmonella} infections in childhood occur in two major forms: (1) gastroenteritis (including food poisoning), which may be complicated by sepsis and focal supplicative complications; and (2) enteric fever (typhoid fever and paratyphoid fever) (see section on Typhoid Fever and Paratyphoid Fever). Although the incidence of typhoid fever has decreased in the United States, the incidence of \textit{Salmonella} gastroenteritis has greatly increased in the past 15–20 years. The highest attack rates occur in children younger than age 6 years, with a peak in the age group from 6 months to 2 years.

Salmonellae are widespread in nature, infecting domestic and wild animals. Fowl and reptiles have a particularly high carriage rate. Transmission results primarily from ingestion of contaminated food. Transmission from human to human occurs by the fecal-oral route via contaminated food, water, and fomites. Numerous foods, including meats, milk, cheese, ice cream, chocolate, contaminated egg powder, and frozen whole egg preparations used to make ice cream, custards, and mayonnaise are associated with outbreaks. Eggs with contaminated shells that are consumed raw or undercooked have been incriminated in outbreaks and sporadic cases. Animal contact also can be a source for \textit{Salmonella}.

Because salmonellae are susceptible to gastric acidity, the elderly, infants, and patients taking antacids or \textit{H}_2-blocking drugs are at increased risk for infection. Most cases of \textit{Salmonella} meningitis (80%) and bacteremia occur in infancy. Newborns may acquire the infection from their mothers during delivery and may precipitate outbreaks in nurseries. Newborns are at special risk for developing meningitis.

\section*{Clinical Findings}

\subsection*{A. Symptoms and Signs}

There is a very wide range of severity of infection. Infants usually develop fever, vomiting, and diarrhea. The older child also may complain of headache, nausea, and abdominal pain. Stools are often watery or may contain mucus and, in some instances, blood, suggesting shigellosis. Drowsiness and disorientation may be associated with meningismus. Convulsions occur less frequently than with shigellosis. Splenomegaly occasionally occurs. In the usual case, diarrhea is moderate and subsides after 4–5 days, but it may be protracted.

\subsection*{B. Laboratory Findings}

Diagnosis is made by isolation of the organism from stool, blood, or, in some cases, from urine, CSF, or pus from a suppurative lesion. The WBC count usually shows a polymorphonuclear leukocytosis but may show leukopenia. \textit{Salmonella} isolates should be reported to public health authorities for epidemiologic purposes.

\section*{Differential Diagnosis}

In staphylococcal food poisoning, the incubation period is shorter (2–4 hours) than in \textit{Salmonella} food poisoning (12–24 hours). Fever is absent, and vomiting rather than diarrhea is the main symptom. In shigellosis, many polymorphonuclear leukocytes usually are seen on a stained smear of stool, and the peripheral WBC count is more likely to slow a marked left shift, although some cases of salmonellosis are indistinguishable from shigellosis. \textit{Campylobacter} gastroenteritis commonly resembles salmonellosis clinically. Culture of the stools is necessary to distinguish the causes of bacterial gastroenteritis.

\section*{Complications}

Unlike most types of infectious diarrhea, salmonellosis is frequently accompanied by bacteremia, especially in newborns and infants. Septicemia with extraintestinal infection is seen, most commonly with \textit{Salmonella choleraesuis} but also with \textit{Salmonella enterica}, typhimurium, and paratyphi serotypes. The organism may spread to any tissue and may cause arthritis, osteomyelitis, cholecystitis, endocarditis, meningitis, pericarditis, pneumonia, or pyelonephritis. Patients with sickle cell anemia or other hemoglobinopathies have a predilection for the development of osteomyelitis. Severe dehydration and shock are more likely to occur with shigellosis but may occur with \textit{Salmonella} gastroenteritis.

\section*{Prevention}

Measures for the prevention of \textit{Salmonella} infections include thorough cooking of foodstuffs derived from contaminated sources, adequate refrigeration, control of infection among domestic animals, and meticulous meat and poultry inspections. Raw and undercooked fresh eggs should be avoided. Food handlers and child care workers with salmonellosis should have three negative stool cultures before resuming work. Asymptomatic children, who have recovered from \textit{Salmonella} infection, do not need exclusion.
TYPHOID FEVER & PARATYPHOID FEVER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Insidious or acute onset of headache, anorexia, vomiting, constipation or diarrhea, ileus, and high fever.
- Meningismus, splenomegaly, and rose spots.
- Leukopenia; positive blood, stool, bone marrow, and urine cultures.

General Considerations

Typhoid fever is caused by the gram-negative bacillus *Salmonella typhi*. Paratyphoid fevers, which are usually milder but may be clinically indistinguishable, are caused by *S paratyphi A*, *Salmonella schottmulleri*, or *Salmonella hirschfeldii* (formerly *S paratyphi A*, B, and C). Children have a shorter incubation period than do adults (usually 5–8 days instead of 8–14 days). The organism enters the body through the walls of the intestinal tract and, following a transient bacteremia, multiplies in the reticuloendothelial cells of the liver and spleen. Persistent bacteremia and symptoms then follow. Reinfection of the intestine occurs as organisms are excreted in the bile. Bacterial emboli produce
the characteristic skin lesions (rose spots). Typhoid fever is transmitted by the fecal-oral route and by contamination of food or water. Unlike other Salmonella species, there are no animal reservoirs of S typhi; each case is the result of direct or indirect contact with the organism or with an individual who is actively infected or a chronic carrier.

About 460 cases per year were reported in the United States in 2010, 80% of which are acquired during foreign travel.

► Clinical Findings

A. Symptoms and Signs

In children, the onset of typhoid fever usually is sudden rather than insidious, with malaise, headache, crampy abdominal pains and distention, and sometimes constipation followed within 48 hours by diarrhea, high fever, and toxemia. An encephalopathy may be seen with irritability, confusion, delirium, and stupor. Vomiting and meningeal symptoms may be prominent in infants and young children. The classic lengthy three-stage disease seen in adult patients often is shorted in children. The prodrome may last only 2–4 days, the toxic stage only 2–3 days, and the defervescence stage 1–2 weeks.

During the prodromal stage, physical findings may be absent, but abdominal distention and tenderness, meningeal signs, mild hepatomegaly, and minimal splenomegaly may be present. The typical typhoidal rash (rose spots) is present in 10%–15% of children. It appears during the second week of the disease and may erupt in crops for the succeeding 10–14 days. Rose spots are erythematous maculopapular lesions 2–3 mm in diameter that blanch on pressure. They are found principally on the trunk and chest and they generally disappear within 3–4 days. The lesions usually number fewer than 20.

B. Laboratory Findings

Typhoid bacilli can be isolated from many sites, including blood, stool, urine, and bone marrow. Blood cultures are positive in 50%–80% of cases during the first week and less often later in the illness. Stool cultures are positive in about 50% of cases after the first week. Urine and bone marrow cultures also are valuable. Most patients will have negative cultures (including stool) by the end of a 6-week period. Serologic tests (Widal reaction) are not as useful as cultures because both false-positive and false-negative results occur. Leukopenia is common in the second week of the disease, but in the first week, leukocytosis may be seen. Proteinuria, mild elevation of liver enzymes, thrombocytopenia, and DIC are common.

► Differential Diagnosis

Typhoid and paratyphoid fevers must be distinguished from other serious prolonged fevers. These include typhus, brucellosis, malaria, tularemia, tuberculosis, psittacosis, vasculitis, lymphoma, mononucleosis, and Kawasaki disease. The diagnosis of typhoid fever often is made clinically in developing countries, but the accuracy of clinical diagnosis is variable. In developed countries, where typhoid fever is uncommon and physicians are unfamiliar with the clinical picture, the diagnosis often is not suspected until late in the course. Positive cultures confirm the diagnosis.

► Complications

The most serious complications of typhoid fever are gastrointestinal hemorrhage (2%–10%) and perforation (1%–3%). They occur toward the end of the second week or during the third week of the disease.

Intestinal perforation is one of the principal causes of death. The site of perforation generally is the terminal ileum or cecum. The clinical manifestations are indistinguishable from those of acute appendicitis, with pain, tenderness, and rigidity in the right lower quadrant.

Bacterial pneumonia, meningitis, septic arthritis, abscesses, and osteomyelitis are uncommon complications, particularly if specific treatment is given promptly. Shock and electrolyte disturbances may lead to death.

About 1%–3% of patients become chronic carriers of S typhi. Chronic carriage is defined as excretion of typhoid bacilli for more than a year, but carriage is often lifelong. Adults with underlying biliary or urinary tract disease are much more likely than children to become chronic carriers.

► Prevention

Routine typhoid vaccine is not recommended in the United States but should be considered for foreign travel to endemic areas. An attenuated oral typhoid vaccine produced from strain Ty21a has better efficacy and causes minimal side effects but is not approved for children younger than age 6 years. The vaccine is repeated after 5 years. A capsular polysaccharide vaccine (ViCPS) requires one intramuscular injection and may be given to children age 2 years and older. (See Chapter 10.)

► Treatment

A. Specific Measures

Third-generation cephalosporins such as cefotaxime (150 mg/kg divided in three doses), azithromycin (10 mg/kg on day 1, followed by 5 mg/kg for 7 days), or a fluoroquinolone are used for presumptive therapy. Antimicrobial susceptibility testing and local experience are used to direct subsequent therapy. Equally effective regimens for susceptible strains include the following: TMP-SMX (10 mg/kg trimethoprim and 50 mg/kg
sulfamethoxazole per day orally in two or three divided doses), amoxicillin (100 mg/kg/d orally in four divided doses), and ampicillin (100–200 mg/kg/d intravenously in four divided doses). Aminoglycosides and first- and second-generation cephalosporins are clinically ineffective regardless of in vitro susceptibility results. Ciprofloxacin or other fluoroquinolones are efficacious but not approved in children, but may be used for multiply resistant strains. Treatment duration is 14–21 days. Patients may remain febrile for 3–5 days even with appropriate therapy.

**B. General Measures**

General support of the patient is exceedingly important and includes rest, good nutrition and hydration, and careful observation, with particular regard to evidence of intestinal bleeding or perforation. Blood transfusions may be needed even in the absence of frank hemorrhage.

**Prognosis**

A prolonged convalescent carrier stage may occur in children. Three negative cultures after all antibiotics have been stopped are required before contact precautions are stopped. With early antibiotic therapy, the prognosis is excellent, and the mortality rate is less than 1%. Relapse occurs 1–3 weeks after appropriate therapy.

**General Considerations**

Shigellae are nonmotile gram-negative rods of the family Enterobacteriaceae and are closely related to *E. coli*. The genus *Shigella* is divided into four species: *S. dysenteriae*, *Shigella flexneri*, *Shigella boydii*, and *Shigella sonnei*. Approximately 15,000 to 20,000 cases of shigellosis are reported each year in the United States. *S. sonnei* followed by *S. flexneri* are the most common isolates.

*S. dysenteriae*, which causes the most severe diarrhea of all species and the greatest number of extraintestinal complications, accounts for less than 1% of all *Shigella* infections in the United States.

Shigellosis may be a serious disease, particularly in young children, and without supportive treatment an appreciable mortality rate results. In older children and adults, the disease tends to be self-limited and milder. *Shigella* is usually transmitted by the fecal-oral route. Food- and water-borne outbreaks are increasing in occurrence, but are less important overall than person-to-person transmission. The disease is very communicable—as few as 200 bacteria can produce illness in an adult. The secondary attack rate in families is high, and shigellosis is a serious problem in day care centers and custodial institutions. *Shigella* organisms produce disease by invading the colonic mucosa, causing mucosal ulcerations and microabscesses. A plasmid-encoded gene is required for enterotoxin production, chromosomal genes are required for invasiveness, and smooth lipopolysaccharides are required for virulence. An experimental vaccine is under development and is safe and immunogenic in young children.

**Clinical Findings**

**A. Symptoms and Signs**

The incubation period of shigellosis is usually 2–4 days. Onset is abrupt, with abdominal cramps, urgency, tenesmus, chills, fever, malaise, and diarrhea. Hallucinations and seizures sometimes accompany high fever. In severe forms, blood and mucus are seen in small stools (dysentery), and meningismus and convulsions may occur. In older children, the disease may be mild and may be characterized by watery diarrhea without blood. In young children, a fever of 39.4–40°C is common. Rarely there is rectal prolapse. Symptoms generally last 3–7 days.

**B. Laboratory Findings**

The total WBC count varies, but often there is a marked shift to the left. The stool may contain gross blood and mucus, and many neutrophils are seen if mucus from the stool is examined microscopically. Stool cultures are usually positive; however, they may be negative because the organism is somewhat fragile and present in small numbers late in the disease, and because laboratory techniques are suboptimal for the recovery of shigellae.
Differential Diagnosis

Diarrhea due to rotavirus infection is a winter rather than a summer disease. Usually children with viral gastroenteritis are not as febrile or toxic as those with shigellosis, and the stool does not contain gross blood or neutrophils. Intestinal infections caused by Salmonella or Campylobacter are differentiated by culture. Grossly bloody stools in a patient without fever or stool leukocytes suggest E. coli O157:H7 infection. Amoebic dysentery is diagnosed by microscopic examination of fresh stools or sigmoidoscopy specimens. Intussusception is characterized by an abdominal mass (so-called currant jelly stools) without leukocytes, and by absence of initial fever. Mild shigellosis is not distinguishable clinically from other forms of infectious diarrhea.

Complications

Dehydration, acidosis, shock, and renal failure are the major complications. In some cases, a chronic form of dysentery occurs, characterized by mucoid stools and poor nutrition. Bacteremia and metastatic infections are rare but serious complications. Febrile seizures are common. Fulminating fatal dysentery and hemolytic-uremic syndrome occur rarely. Reiter syndrome may follow S. flexneri infection.

Treatment

A. Specific Measures

Resistance to TMP-SMX (10 mg/kg/d trimethoprim and 50 mg/kg/d sulfamethoxazole, given in two divided doses orally for 5 days) and ampicillin (100 mg/kg/d divided in four doses) is common and limits the use of these drugs to cases where results of susceptibility testing are known. Amoxicillin is not effective. Parenteral ceftriaxone is effective. Azithromycin (12 mg/kg/d on day 1, then 6 mg/kg/d for 2 days) is effective, but laboratories do not routinely perform susceptibility testing for azithromycin. Ciprofloxacin (500 mg, given twice daily for 5 days) is efficacious in adults but is not approved for use in children. However, it may be used in children who remain symptomatic and in need of therapy, and when multiply resistant strains limit other preferred choices. Successful treatment reduces the duration of fever, cramping, and diarrhea and terminates fecal excretion of Shigella. Presumptive therapy should be limited to children with classic shigellosis or known outbreaks. Afebrile children with bloody diarrhea are more commonly infected with EHEC. Antimicrobial therapy of EHEC may increase the likelihood of hemolytic-uremic syndrome, and is not recommended.

B. General Measures

In severe cases, immediate rehydration is critical. A mild form of chronic malabsorption syndrome may supervene and require prolonged dietary control.

Prognosis

The prognosis is excellent if vascular collapse is treated promptly by adequate fluid therapy. The mortality rate is high in very young, malfnourished infants who do not receive fluid and electrolyte therapy. Convalescent fecal excretion of Shigella lasts 1–4 weeks in patients not receiving antimicrobial therapy. Long-term carriers are rare.

Cholera

General Considerations

Cholera is an acute diarrheal disease caused by the gram-negative organism Vibrio cholerae. It is transmitted by contaminated water or food, especially contaminated shellfish. Epidemics are common in impoverished areas where hygiene and safe water supply are limited. Typical disease is generally so dramatic that in endemic areas the diagnosis is obvious. Individuals with mild illness and young children may play an important role in transmission of the infection.

Asymptomatic infection is far more common than clinical disease. In endemic areas, rising titers of vibriocidal antibody are seen with increasing age. Infection occurs in individuals with low titers. The age-specific attack rate is highest in children younger than age 5 years and declines with age. Cholera is unusual in infancy.

Cholera toxin is a protein enterotoxin that is primarily responsible for symptoms. Cholera toxin binds to a regulatory subunit of adenyl cyclase in enterocytes, causing increased cyclic adenosine monophosphate and an outpouring of NaCl and water into the lumen of the small bowel.
Nutritional status is an important factor determining the severity of the diarrhea. Duration of diarrhea is prolonged in adults and children with severe malnutrition.

Cholera is endemic in India and southern and Southeast Asia and in parts of Africa. The most recent pandemic, caused by the El Tor biotype of *V. cholerae* 01, began in 1961 in Indonesia. Epidemic cholera spread in Central and South America, with a total of 1 million cases and 9500 deaths reported through 1994. A severe cholera outbreak is ongoing in Haiti since October 2010. More than 500,000 cases and 6000 deaths are estimated. *V. cholerae* serogroups 0139 has been recognized in Asia as a cause of cholera illness. Cases in the United States occurred in the course of foreign travel or as a result of consumption of contaminated imported food. Cholera is increasingly associated with consumption of shellfish. Interstate shipment of oysters has resulted in cholera in several inland states. Cholera is now rare in the United States with 10 to 15 cases per year reported.

*V. cholerae* is a natural inhabitant of shellfish and copepods in estuarine environments. Seasonal multiplication of *V. cholerae* may provide a source of outbreaks in endemic areas. Chronic cholera carriers are rare. The incubation period is short, usually 1–3 days.

### Clinical Findings

#### A. Symptoms and Signs

Many patients infected with *V. cholerae* have mild disease, with 1%–2% developing severe diarrhea. During severe cholera, there is a sudden onset of massive, frequent, watery stools, generally light gray in color (so-called rice-water stools) and containing some mucus but no pus. Vomiting may be projectile and is not accompanied by nausea. Within 2–3 hours, the tremendous loss of fluids results in life-threatening dehydration, hypochloremia, and hypokalemia, with marked weakness and collapse. Renal failure with uremia and irreversible peripheral vascular collapse will occur if fluid therapy is not administered. The illness lasts 1–7 days and is shortened by appropriate antibiotic therapy.

#### B. Laboratory Findings

Markedly elevated hemoglobin (20 g/dL) and marked acidosis, hypochloremia, and hyponatremia are seen. Stool sodium concentration may range from 80 to 120 mEq/L. Culture confirmation requires specific media and takes 16–18 hours for a presumptive diagnosis and 36–48 hours for a definitive bacteriologic diagnosis.

### Prevention

Cholera vaccine is available outside of the United States and provides 50%–75% efficacy. Protection lasts 3–6 months. Cholera vaccine is not generally recommended for travelers.

Tourists visiting endemic areas are at little risk if they exercise caution in what they eat and drink and maintain good personal hygiene. In endemic areas, all water and milk must be boiled, food protected from flies, and sanitary precautions observed. Simple filtration of water is highly effective in reducing cases. Thorough cooking of shellfish prevents transmission. All patients with cholera should be isolated.

Chemoprophylaxis is indicated for household and other close contacts of cholera patients. It should be initiated as soon as possible after the onset of the disease in the index patient. Tetracycline (500 mg/d for 5 days) is effective in preventing infection. TMP-SMX may be substituted in children.

### Treatment

Physiologic saline or lactated Ringer solution should be administered intravenously in large amounts to restore blood volume and urine output and prevent irreversible shock. Potassium supplements are required. Sodium bicarbonate, given intravenously, also may be needed initially to overcome profound metabolic acidosis from bicarbonate loss in the stool. Moderate dehydration and acidosis can be corrected in 3–6 hours by oral therapy alone, because the active glucose transport system of the small bowel is normally functional. The optimal composition of the oral solution (in milliequivalents per liter [mEq/L]) is as follows: Na+, 90; Cl−, 80; and K+, 20 (with glucose, 110 mmol/L).

Treatment with tetracycline (50 mg/kg/d orally in four divided doses for 2–5 days) or azithromycin (10 mg/kg/d in one dose for 1–5 days) shortens the duration of the disease in children and prevents clinical relapse but is not as important as fluid and electrolyte therapy. Tetracycline resistance occurs in some regions, and ciprofloxacin may be used depending on local resistance patterns. TMP-SMX or azithromycin should be used in children younger than age 9 years.

### Prognosis

With early and rapid replacement of fluids and electrolytes, the case fatality rate is 1%–2% in children. If significant symptoms appear and no treatment is given, the mortality rate is over 50%.
**CAMPYLOBACTER INFECTION**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Fever, vomiting, abdominal pain, diarrhea.
- Presumptive diagnosis by darkfield or phase contrast microscopy of stool wet mount or modified Gram stain.
- Definitive diagnosis by stool culture.

**General Considerations**

*Campylobacter* species are small gram-negative, curved or spiral bacilli that are commensals or pathogens in many animals. *Campylobacter jejuni* frequently causes acute enteritis in humans. In the 1990s, *C. jejuni* was responsible for 3%–11% of cases of acute gastroenteritis in North America and Europe. In many areas, enteritis due to *C. jejuni* is more common than that due to *Salmonella* or *Shigella*. *Campylobacter fetus* causes bacteremia and meningitis in immunocompromised patients. *C. fetus* may cause maternal fever, abortion, stillbirth, and severe neonatal infection. *Helicobacter pylori* (previously called *Campylobacter pylori*) causes gastritis and peptic ulcer disease in both adults and children (see Chapter 21).

*Campylobacter* colonizes domestic and wild animals, especially poultry. Numerous cases have been associated with sick puppies or other animal contacts. Contaminated food and water, improperly cooked poultry, and person-to-person spread by the fecal-oral route are common routes of transmission. Outbreaks associated with day care centers, contaminated water supplies, and raw milk have been reported. Newborns may acquire the organism from their mothers at delivery.

**Clinical Findings**

**A. Symptoms and Signs**

*C. jejuni* enteritis can be mild or severe. In tropical countries, asymptomatic stool carriage is common. The incubation period is usually 1–7 days. The disease usually begins with sudden onset of high fever, malaise, headache, abdominal cramps, nausea, and vomiting. Diarrhea follows and may be watery or bile-stained, mucoid, and bloody. The illness is self-limiting, lasting 2–7 days, but relapses may occur. Without antimicrobial treatment, the organism remains in the stool for 1–6 weeks.

**B. Laboratory Findings**

The peripheral WBC count generally is elevated, with many band forms. Microscopic examination of stool reveals erythrocytes and pus cells.

Isolation of *C. jejuni* from stool is not difficult but requires selective agar, incubation at 42°C rather than 35°C, and incubation in an atmosphere of about 5% oxygen and 5% CO₂ (candle jar is satisfactory).

**Differential Diagnosis**

*Campylobacter* enteritis may resemble viral gastroenteritis, salmonellosis, shigellosis, amebiasis, or other infectious diarrheas. Because it also mimics ulcerative colitis, Crohn disease, intussusception, and appendicitis, mistaken diagnosis can lead to unnecessary diagnostic testing or surgery.

**Complications**

The most common complication is dehydration. Other uncommon complications include erythema nodosum, convulsions, reactive arthritis, bacteremia, urinary tract infection, and cholecystitis. Guillain-Barré syndrome may follow *C. jejuni* infection by 1–3 weeks.

**Prevention**

No vaccine is available. Hand washing and adherence to basic food sanitation practices help prevent disease. Hand washing and cleaning of kitchen utensils after contact with raw poultry are important.

**Treatment**

Treatment of fluid and electrolyte disturbances is important. Antimicrobial treatment with erythromycin in children (30–50 mg/kg/d orally in four divided doses for 5 days), azithromycin (10 mg/kg/d orally once daily) for 3 days, or ciprofloxacin terminates fecal excretion. Fluoroquinolone-resistant *C. jejuni* are now common worldwide. Therapy given early in the course of the illness will shorten the duration of symptoms but is unnecessary if given later. Antimicrobials used for shigellosis, such as TMP-SMX and ampicillin, are inactive against *Campylobacter*. Supportive therapy is sufficient in most cases.

**Prognosis**

The outlook is excellent if dehydration is corrected and misdiagnosis does not lead to inappropriate diagnostic or surgical procedures.

TULAREMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- A cutaneous or mucous membrane lesion at the site of inoculation and regional lymph node enlargement.
- Sudden onset of fever, chills, and prostration.
- History of contact with infected animals, principally wild rabbits, or history of tick exposure.
- Positive culture or immunofluorescence from mucocutaneous ulcer or regional lymph nodes.
- High serum antibody titer.

General Considerations

Tularemia is caused by Francisella tularensis, a gram-negative organism usually acquired directly from infected animals (principally wild rabbits) or by the bite of an infected tick. Occasionally infection is acquired from infected domestic dogs or cats; by contamination of the skin or mucous membranes with infected blood or tissues; by inhalation of infected material; by bites of fleas or deer flies that have been in contact with infected animals; or by ingestion of contaminated meat or water. The incubation period is short, usually 3–7 days, but may vary from 2 to 25 days.

Ticks are the most important vector of tularemia and rabbits are the classic vector. It is important to seek a history of rabbit hunting, skinning, or food preparation in any patient who has a febrile illness with tender lymphadenopathy, often in the region of a draining skin ulcer.

Prevention

Children should be protected from insect bites, especially those of ticks, fleas, and deer flies, by the use of proper clothing and repellents. Because rabbits are the source of most human infections, the dressing and handling of such game should be performed with great care. Rubber gloves should be worn by hunters or food handlers when handling carcasses of wild rabbits. If contact occurs, thorough washing with soap and water is indicated. For postexposure prophylaxis from an intentional release of F. tularensis (bioterrorism), a 14-day course of doxycycline or ciprofloxacin is recommended (children less than 8 years should not receive doxycycline unless benefits outweigh risks; in children less than 18 years ciprofloxacin is not approved for this indication—weigh benefits and risk).

Clinical Findings

A. Symptoms and Signs

Several clinical types of tularemia occur in children. Sixty percent of infections are of the ulceroglandular form and start as a reddened papule that may be pruritic, quickly ulcerates, and is not very painful. Soon, the regional lymph nodes become large and tender. Fluactuation quickly follows. There may be marked systemic symptoms, including high fever, chills, weakness, and vomiting. Pneumonitis occasionally accompanies the ulceroglandular form or may be seen as the sole manifestation of infection (pneumonic form). A detectable skin lesion may be absent, and localized lymphoid enlargement may exist alone (glandular form). Oculoglandular and oropharyngeal forms also occur. The latter is characterized by tonsillitis, often with membrane formation, cervical adenopathy, and high fever. In the absence of a primary ulcer or localized lymphadenitis, a prolonged febrile disease reminiscent of typhoid fever can occur (typhoidal form). Splenomegaly is common in all forms.

B. Laboratory Findings

F. tularensis can be recovered from ulcers, regional lymph nodes, and sputum of patients with the pneumatic form. However, the organism grows only on an enriched medium (blood-cystine-glucose agar), and laboratory handling is dangerous owing to the risk of airborne transmission to laboratory personnel. Immunofluorescent staining of biopsy material or aspirates of involved lymph nodes is diagnostic, although it is not widely available.

The WBC count is not remarkable. Agglutinins are present after the second week of illness, and in the absence of a positive culture their development confirms the diagnosis. A tube agglutination antibody titer of 1:160 or greater or a microagglutination titer of 1:128 or higher is considered presumptively positive for the diagnosis of tularemia. Confirmation of disease is established by demonstration of a fourfold antibody titer rise between acute and convalescent serum samples. PCR of blood, lymph node aspirate, or tissue may be available through State Health Departments.

Differential Diagnosis

The typhoidal form of tularemia may mimic typhoid, brucellosis, miliary tuberculosis, Rocky Mountain spotted fever, and mononucleosis. Pneumonic tularemia resembles atypical or mycotic pneumonia. The ulceroglandular type of tularemia resembles pyoderma caused by staphylococci or streptococci, plague, anthrax, and cat-scratch fever. The oropharyngeal type must be distinguished from streptococcal or diphtheritic pharyngitis, mononucleosis, herpangina, or other viral pharyngitides.
INFECTIONS: BACTERIAL & SPIROCHETAL

Treatment

A. Specific Measures

Historically, streptomycin was the drug of choice. However, gentamicin is efficacious, more available, and familiar to clinicians. A 10-day course is usually sufficient, although more severe infections may need longer therapy. Doxycycline is effective, but relapse rates are higher. Doxycycline is not usually recommended for children younger than 8 years of age unless benefits of use outweigh the risk of dental staining. Doxycycline is a static (as opposed to cidal) agent and should be given for at least 14 days. Ciprofloxacin also can be used in patients with less severe disease. Ciprofloxacin is not approved for children younger than 18 years, and is not usually recommended in children unless benefits outweigh risks.

B. General Measures

Antipyretics and analgesics may be given as necessary. Skin lesions are best left open. Glandular lesions occasionally require incision and drainage.

Prognosis

The prognosis is excellent in most cases of tularemia that are recognized early and treated appropriately.

Prevention

Proper disposal of household and commercial wastes and chemical control of rats are basic elements of plague prevention. Flea control is instituted and maintained with liberal use of insecticides. Children vacationing in remote camping areas should be warned not to handle dead or dying animals. Domestic cats that roam freely in suburban areas may contact infected wild animals and acquire infected fleas. There is no commercially available vaccine for plague.

All persons who have been exposed to plague in the previous 6 days (via personal contact with an infected person, contact with plague infected fleas, or exposure to infected tissues) should be given antimicrobial prophylaxis or be instructed to closely monitor themselves for fever or other symptoms and report any illness or any fever to their physician. Persons who have close personal contact (< 2 m) with a person with pneumonic plague should receive antimicrobial prophylaxis for 7 days from the last exposure. Doxycycline or ciprofloxacin are the recommended agents for prophylaxis. For children younger than 8 years, TMP-SMX is an alternative agent but the efficacy is unknown. Chloramphenicol is also an alternative agent. For persons who have had a known or suspected exposure to plague-infected fleas in the previous week, the same antimicrobial regimen can be used for prophylaxis. Patients on prophylaxis should still seek prompt medical care for onset of fever or other illness.

PLAQUE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Sudden onset of fever, chills, and prostration.
- Regional lymphadenitis with suppuration of nodes (bubonic form).
- Hemorrhage into skin and mucous membranes and shock (septicemia).
- Cough, dyspnea, cyanosis, and hemoptysis (pneumonia).
- History of exposure to infected animals.

General Considerations

Plague is an extremely serious acute infection caused by a gram-negative bacillus, Yersinia pestis. It is a disease of rodents that is transmitted to humans by flea bites. Plague bacilli have been isolated from ground squirrels, prairie dogs, and other wild rodents in many of the western and southwestern states in the United States. Most cases have come from New Mexico, Arizona, Colorado, and California. Direct contact with rodents, rabbits, or domestic cats may transmit fleas infected with plague bacilli. Most cases occur from June through September. Human plague in the United States appears to occur in cycles that reflect cycles in wild animal reservoirs.

Clinical Findings

A. Symptoms and Signs

Plague assumes several clinical forms; the two most common are bubonic and septicemic. Pneumonic plague, the form that occurs when organisms enter the body through the respiratory tract, is uncommon.

1. Bubonic plague—Bubonic plague begins after an incubation period of 2–8 days with a sudden onset of high fever, chills, headache, vomiting, and marked delirium or clouding of consciousness. A less severe form also exists, with a less precipitous onset, but with progression over several days
to severe symptoms. Although the flea bite is rarely seen, the regional lymph node, usually inguinal and unilateral, is/are painful and tender, 1–5 cm in diameter. The node usually suppurates and drains spontaneously after 1 week. The plague bacillus produces endotoxin that causes vascular necrosis. Bacilli may overwhelm regional lymph nodes and enter the circulation to produce septicemia. Severe vascular necrosis results in widely disseminated hemorrhage in skin, mucous membranes, liver, and spleen. Myocarditis and circulatory collapse may result from damage by the endotoxin. Plague meningitis or pneumonia may occur following bacteremic spread from an infected lymph node.

2. Septicemic plague—Plague may initially present as septicemia without evidence of lymphadenopathy. In some series, 25% of cases are initially septicemic. Septicemic plague carries a worse prognosis than bubonic plague, largely because it is not recognized and treated early. Patients may present initially with a nonspecific febrile illness characterized by fever, myalgia, chills, and anorexia. Plague is frequently complicated by secondary seeding of the lung causing plague pneumonia.

3. Primary pneumonic plague—Inhalation of Y pestis bacilli causes primary plague pneumonia. This form of plague has been transmitted to humans from cats with pneumonic plague and would be the form of plague most likely seen after aerosolized release of Y pestis in a bioterrorist incident. After an incubation of 1–6 days, the patient develops fever, cough, shortness of breath, and the production of bloody, watery, or purulent sputum. Gastrointestinal symptoms are sometimes prominent. Because the initial focus of infection is the lung, buboes are usually absent; occasionally cervical buboes may be seen.

B. Laboratory Findings

Aspirate from a bubo contains bipolar-staining gram-negative bacilli. Pus, sputum, and blood all yield the organism. Rapid diagnosis can be made with fluorescent antibody detection or polymerase chain reaction (PCR) on clinical specimens. Confirmation is made by culture or serologic testing. Laboratory infections are common enough to make bacterial isolation dangerous. Cultures are usually positive within 48 hours. Paired acute and convalescent sera may be tested for a fourfold antibody rise in those cases with negative cultures.

Differential Diagnosis

The septic phase of the disease may be confused with illnesses such as meningococcemia, sepsis caused by other bacteria, and rickettsioses. The bubonic form resembles tularemia, anthrax, cat-scratch fever, streptococcal adenitis, and cellulitis. Primary gastroenteritis and appendicitis may have to be distinguished.

Treatment

A. Specific Measures

Streptomycin or gentamicin for 7–10 days (or until several days after defervescence) is effective. For patients not requiring parenteral therapy, doxycycline, ciprofloxacin or chloramphenicol may be given. Doxycycline is not usually recommended for children younger than 8 years of age and ciprofloxacin is not usually recommended for children less than 18 years of age unless benefits of use outweigh the risk. However, plague is a potentially life-threatening condition and benefits of use of these agents outweigh potential risks. Plague bacilli that are multiply resistant to antimicrobials are uncommon but of serious concern.

Mortality is extremely high in septicemic and pneumonic plague if specific antibiotic treatment is not started in the first 24 hours of the disease.

Every effort should be made to effect resolution of buboes without surgery. Pus from draining lymph nodes is infectious.

B. General Measures

State health officials should be notified immediately about suspected cases of plague. Pneumonic plague is highly infectious, and droplet isolation is required until the patient has been on effective antimicrobial therapy for 48 hours. All contacts of patients with pneumonic plague should receive antibiotic prophylaxis for 7 days after the last exposure. Contacts should see a physician immediately for any illness or fever.

Prognosis

The mortality rate in untreated bubonic plague is about 50%. The mortality rate for treated pneumonic plague is 50%–60%. Recent mortality rates in New Mexico were 3% for bubonic plague and 71% for the septicemic form.

Centers for Disease Control and Prevention (CDC): Plague. Available at: http://www.cdc.gov/ncidod/dvbid/plague

HAEMOPHILUS INFLUENZAE TYPE B INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Purulent meningitis in children younger than age 4 years with direct smears of CSF showing gram-negative pleomorphic rods.
► Acute epiglottitis: high fever, drooling, dysphagia, aphony, and stridor.
► Septic arthritis: fever, local redness, swelling, heat, and pain with active or passive motion of the involved joint in a child 4 months to 4 years of age.
► Cellulitis: sudden onset of fever and distinctive cellulitis in an infant, often involving the cheek or periorbital area.
► In all cases, a positive culture from the blood, CSF, or aspirated pus confirms the diagnosis.

► General Considerations

*H* influenzae* type b* (Hib) has become uncommon because of widespread immunization in early infancy. The 99% reduction in incidence seen in many parts of the United States is due to high rates of vaccine coverage and reduced nasopharyngeal carriage after vaccination. Forty percent of cases occur in children younger than 6 months who are too young to have completed a primary immunization series. Hib may cause meningitis, bacteremia, epiglottitis (supraglottic group), septic arthritis, periorbital and facial cellulitis, pneumonia, and pericarditis.

Disease due to *H* influenzae* types a, c, d, e, f, or unencapsulated strains is rare, but it now accounts for a larger proportion of positive culture results. Third-generation cephalosporins are preferred for initial therapy of Hib infections. Ampicillin is adequate for culture-proved Hib susceptible strains.

Unencapsulated, nontypeable *H* influenzae frequently colonize the mucous membranes and cause otitis media, sinusitis, bronchitis, and pneumonia in children and adults. Bacteremia is uncommon. Neonatal sepsis similar to early-onset GBS is recognized. Obstetric complications of chorioamnionitis and bacteremia are usually the source of neonatal cases.

Ampicillin resistance occurs in 25%–40% of nontypeable *H* influenzae. Beta-lactamase-negative, ampicillin-resistant (BLNAR) *H* influenzae has emerged as a clinically important pathogen in Europe, Japan, and Canada. In the United States, the prevalence of BLNAR strains currently remains low at around 3%.

► Prevention

Several carbohydrate protein conjugate Hib vaccines are currently available (see Chapter 10).

The risk of invasive Hib disease is highest in unimmunized, or partially immunized, household contacts who are younger than 4 years of age. The following situations require rifampin chemoprophylaxis of all household contacts (except pregnant women) to eradicate potential nasopharyngeal colonization with Hib and limit risk of invasive disease: (1) families where at least one household contact is younger than age 4 years and either unimmunized or incompletely immunized against Hib; (2) an immunocompromised child (of any age or immunization status) resides in the household; or (3) a child younger than age 12 months resides in the home and has not received the primary series of the Hib vaccine. Preschool and day care center contacts may need prophylaxis if more than one case has occurred in the center in the previous 60 days (discuss with state health officials). The index case also needs chemoprophylaxis in these situations to eradicate nasopharyngeal colonization unless treated with ceftriaxone or cefotaxime (both are effective in eradication of Hib from the nasopharynx). Household contacts and index cases older than 1 month of age who need chemoprophylaxis should be given rifampin, 20 mg/kg per dose (maximum adult dose, 600 mg) orally, once daily for 4 successive days. Infants who are younger than 1 month should be given oral rifampin (10 mg/kg per dose once daily for 4 days). Rifampin should not be used in pregnant females.

► Clinical Findings

A. Symptoms and Signs

1. Meningitis—Infants usually present with fever, irritability, lethargy, poor feeding with or without vomiting, and a high-pitched cry.
2. Acute epiglottitis—The most useful clinical finding in the early diagnosis of Hib epiglottitis is evidence of dysphagia, characterized by a refusal to eat or swallow saliva and by drooling. This finding, plus the presence of a high fever in a toxic child—even in the absence of a cherry-red epiglottis on direct examination—should strongly suggest the diagnosis and lead to prompt intubation. Stridor is a late sign (see Chapter 19).
3. Septic arthritis—Hib is a common cause of septic arthritis in unimmunized children younger than age 4 years in the United States. The child is febrile and refuses to move the involved joint and limb because of pain. Examination reveals swelling, warmth, redness, tenderness on palpation, and severe pain on attempted movement of the joint.
4. Cellulitis—Cellulitis due to Hib occurs almost exclusively in children between the ages of 3 months and 4 years but is now uncommon as a result of immunization. Fever is usually noted at the same time as the cellulitis, and many infants appear toxic. The cheek or periorbital (preseptal) area is usually involved.

B. Laboratory Findings

The WBC count in Hib infections may be high or normal with a shift to the left. Blood culture is frequently positive. Positive culture of aspirated pus or fluid from the involved site proves the diagnosis. In untreated meningitis, CSF
smear may show the characteristic pleomorphic gram-negative rods.

C. Imaging
A lateral view of the neck may suggest the diagnosis in suspected acute epiglottitis, but misinterpretation is common. Intubation should not be delayed to obtain radiographs. Haziness of maxillary and ethmoid sinuses occurs with orbital cellulitis.

Differential Diagnosis
A. Meningitis
Meningitis must be differentiated from head injury, brain abscess, tumor, lead encephalopathy, and other forms of meningoencephalitis, including mycobacterial, viral, fungal, and bacterial agents.

B. Acute Epiglottitis
In croup caused by viral agents (parainfluenza 1, 2, and 3, respiratory syncytial virus, influenza A, adenovirus), the child has more definite upper respiratory symptoms, cough, hoarseness, slower progression of obstructive signs, and lower fever. Spasmodic croup usually occurs at night in a child with a history of previous attacks. Sudden onset of choking and paroxysmal coughing suggests foreign body aspiration. Retropharyngeal abscess may have to be differentiated from epiglottitis.

C. Septic Arthritis
Differential diagnosis includes acute osteomyelitis, prepatellar bursitis, cellulitis, rheumatic fever, and fractures and sprains.

D. Cellulitis
Erysipelas, streptococcal cellulitis, insect bites, and trauma (including Popsicle panniculitis or other types of freezing injury) may mimic Hib cellulitis. Periorbital cellulitis must be differentiated from paranasal sinus disease without cellulitis, allergic inflammatory disease of the lids, conjunctivitis, and herpes zoster infection.

Complications
A. Meningitis (See Chapter 25)
B. Acute Epiglottitis
The disease may rapidly progress to complete airway obstruction with complications owing to hypoxia. Mediastinal emphysema and pneumothorax may occur.

C. Septic Arthritis
Septic arthritis may result in rapid destruction of cartilage and ankylosis if diagnosis and treatment are delayed. Even with early treatment, the incidence of residual damage and disability after septic arthritis in weight-bearing joints may be as high as 25%.

D. Cellulitis
Bacteremia may lead to meningitis or pyarthrosis.

Treatment
All patients with bacteremic or potentially bacteremic Hib diseases require hospitalization for treatment. The drugs of choice in hospitalized patients are a third-generation cephalosporin (cefotaxime or ceftriaxone) until the sensitivity of the organism is known. Meropenem is an alternative choice.

Persons with invasive Hib disease should be in droplet isolation for 24 hours after initiation of parenteral antibiotic therapy.

A. Meningitis
Therapy is begun as soon as bacterial meningitis has been identified and CSF, blood, and other appropriate cultures have been obtained. Empiric intravenous therapy recommended for meningitis (until organism identified) is vancomycin in combination with either cefotaxime or ceftriaxone. Once the organism has been identified as Haemophilus influenza and the susceptibilities are known, the antibiotic regimen can be tailored accordingly. Most isolates will be susceptible to ceftriaxone or cefotaxime. Meropenem is an alternative agent. Therapy should preferably be given intravenously for the entire course. Ceftriaxone may be given intramuscularly if venous access becomes difficult.

Duration of therapy is 10 days for uncomplicated meningitis. Longer treatment is reserved for children who respond slowly or in whom complications have occurred.

Dexamethasone given immediately after diagnosis and continued for 4 days may reduce the incidence of hearing loss in children with Hib meningitis. The use of dexamethasone is controversial, but when it is used the dosage is 0.6 mg/kg/d in four divided doses for 4 days. Starting dexamethasone more than 6 hours after antibiotics have been initiated is unlikely to provide benefits.

Repeated lumbar punctures are usually not necessary in Hib meningitis. They should be obtained in the following circumstances: unsatisfactory or questionable clinical response, seizure occurring after several days of therapy, and prolonged (7 days) or recurrent fever if the neurologic examination is abnormal or difficult to evaluate.
B. Acute Epiglottitis (See Chapter 19)

C. Septic Arthritis

Initial therapy should include an effective antistaphylococcal antibiotic and cefotaxime or ceftriaxone (dosage as for meningitis) until identification of the organism is made. Cefotaxime or ceftriaxone are the usual agents used once the isolate is known to be Haemophilus and susceptibilities are known. Ampicillin resistance is now common in the United States. Occasionally isolates are resistant to third generation cephalosporins. Meropenem, if the isolate is susceptible, can be used as an alternative. If a child is improved following initial intravenous therapy, transition to oral therapy based on susceptibilities can occur. Possible oral agents should be chosen based on susceptibilities but might include amoxicillin/clavulanate (90–100 mg/kg/d of amoxicillin component in four divided doses every 6 hours). Antibiotics should be administered under supervision to complete a 4-week course (longer if complications or signs and symptoms are unresolved). Alternative agents include second- or third-generation cephalosporins. Drainage of infected joint fluid is an essential part of treatment. In joints other than the hip, this can often be accomplished by one or more needle aspirations. In hip infections—and in arthritis of other joints when treatment is delayed or clinical response is slow—surgical drainage is advised. The joint should be immobilized.

D. Cellulitis, Including Orbital Cellulitis

Initial therapy for orbital cellulitis should be broad spectrum antibiotic therapy. The most likely pathogens may include Streptococcus pneumonia, Streptococcus anginosus, Group A Streptococcus, Staphylococcus aureus, Haemophilus influenzae, and anaerobes. Once the organism is known to be H influenzae orbital and susceptibilities are known, cefotaxime, ceftriaxone, or Meropenem can be used depending on susceptibilities for H influenzae coverage. Mixed infections require additional agents. Therapy is given parenterally for at least 3–7 days (some clinicians treat up to 2 weeks intravenously) followed by oral treatment. There is usually marked improvement after 72 hours of treatment. The total antibiotic course will vary with the severity of the infection, response to therapy, whether or not an abscess was present, and whether or not drainage was performed. A minimum course of 21 days is reasonable in uncomplicated cases without abscess and good therapeutic response, assuming all signs of orbital cellulitis have completely resolved. In cases with severe ethmoid sinusitis and evidence of bony destruction at least a 4-week treatment course is advisable. Complicated cases may require longer treatment courses.

Prognosis

The case fatality rate for Hib meningitis is less than 5%. Young infants have the highest mortality rate. One of the most common neurologic sequelae, developing in 5%–10% of patients with Hib meningitis, is sensorineural hearing loss. Patients with Hib meningitis should have their hearing checked during the course of the illness or shortly after recovery. Children in whom invasive Hib infection develops despite appropriate immunization should have tests to investigate immune function and to rule out HIV. The case fatality rate in acute epiglottitis is 2%–5%. Deaths are associated with bacteremia and the rapid development of airway obstruction. The prognosis for the other diseases requiring hospitalization is good with the institution of early and adequate antibiotic therapy.

PERTUSSIS (WHOOPING COUGH)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Prodromal catarrhal stage (1–3 weeks) characterized by mild cough and coryza, but without fever.
- Persistent staccato, paroxysmal cough ending with a high-pitched inspiratory “whoop.”
- Leukocytosis with absolute lymphocytosis.
- Diagnosis confirmed by PCR or culture of nasopharyngeal secretions.

General Considerations

Pertussis is an acute, highly communicable infection of the respiratory tract caused by Bordetella pertussis and characterized by severe bronchitis. Children usually acquire the disease from symptomatic family contacts. Adults and adolescents who have mild respiratory illness, not recognized as pertussis, frequently are the source of infection. Asymptomatic carriage of B pertussis is not recognized. Infectivity is greatest during the catarrhal and early paroxysmal cough stage (for about 4 weeks after onset).

Pertussis cases have increased in the United States since 2000. In 2007, about 10,000 cases were reported; increased to more than 16,000 cases in 2009, and 27,000 cases in 2010. The morbidity and mortality of pertussis is greatest in young children. Fifty percent of children younger than age 1 year...
with a diagnosis of pertussis are hospitalized. Deaths occur primarily in children less than one year and are increasing in frequency.

The duration of active immunity following natural pertussis is not known. Reinfections are usually milder. Immunity following vaccination wanes in 5–10 years. The majority of young adults in the United States are susceptible to pertussis infection, and disease is probably common but unrecognized. Decreased efficacy of acellular vaccines compared to whole cell vaccines and low rates of immunization in some communities has led to increasing numbers of cases.

*Bordetella parapertussis* and *Bordetella holmesii* cause a similar but milder syndrome.

*B. pertussis* organisms attach to the ciliated respiratory epithelium and multiply there; deeper invasion does not occur. Disease is due to several bacterial toxins, the most potent of which is pertussis toxin, which is responsible for the typical lymphocytosis.

### Clinical Findings

#### A. Symptoms and Signs

The onset of pertussis is insidious, with catarrhal upper respiratory tract symptoms (rhinitis, sneezing, and an irritating cough). Slight fever may be present; temperature greater than 38.3°C suggests bacterial superinfection or another cause of respiratory tract infection. After about 2 weeks, cough becomes paroxysmal, characterized by 10–30 forceful coughs ending with a loud inspiration (the whoop). Infants and adults with otherwise typical severe pertussis often lack characteristic whooping. Vomiting commonly follows a paroxysm. Coughing is accompanied by cyanosis, sweating, prostration, and exhaustion. This stage lasts for 2–4 weeks, with gradual improvement. Paroxysmal coughing may continue for some months and may worsen with intercurrent viral respiratory infection. In adults, older children, and partially immunized individuals, symptoms may consist only of irritating cough lasting 1–2 weeks. Clinical pertussis is milder in immunized children.

#### B. Laboratory Findings

WBC counts of 20,000–30,000/μL with 70%–80% lymphocytes typically appear near the end of the catarrhal stage; and the degree of lymphocytosis correlates with the severity of disease. Severe pulmonary hypertension and hyperleukocytosis (> 70,000/μL) are associated with severe disease and death in young children with pertussis. Many older children and adults with mild infections never demonstrate lymphocytosis. The blood picture may resemble lymphocytic leukemia or leukemoid reactions. Identification of *B. pertussis* by culture or PCR from nasopharyngeal swabs or nasal wash specimens proves the diagnosis. The organism may be found in the respiratory tract in diminishing numbers beginning in the catarrhal stage and ending about 2 weeks after the beginning of the paroxysmal stage. After 4–5 weeks of symptoms, cultures are almost always negative. Culture requires specialized media and careful attention to specimen collection and transport. PCR detection has replaced culture in most pediatric centers because of improved sensitivity, decreased time to diagnosis, and cost. Enzyme-linked immunosorbent assays (ELISAs) for detection of antibody to pertussis toxin or filamentous hemagglutinin may be useful for diagnosis but interpretation of antibody titers may be difficult in previously immunized patients. The chest radiograph reveals thickened bronchi and sometimes shows a “shaggy” heart border.

### Differential Diagnosis

The differential diagnosis of pertussis includes bacterial, tuberculous, chlamydial, and viral pneumonia. The absence of fever in pertussis differentiates this disease from most bacterial infections. Cystic fibrosis and foreign body aspiration may be considerations. Adenoviruses and respiratory syncytial virus may cause paroxysmal coughing with an associated elevation of lymphocytes in the peripheral blood, mimicking pertussis.

### Complications

Bronchopneumonia due to superinfection is the most common serious complication. It is characterized by abrupt clinical deterioration during the paroxysmal stage, accompanied by high fever and sometimes a striking leukemoid reaction with a shift to predominantly polymorphonuclear neutrophils. Atelectasis is a second common pulmonary complication. Atelectasis may be patchy or extensive and may shift rapidly to involve different areas of lung. Intercurrent viral respiratory infection is also a common complication and may provoke worsening or recurrence of paroxysmal coughing. Otitis media is common. Residual chronic bronchietasis is infrequent despite the severity of the illness. Apnea and sudden death may occur during a particularly severe paroxysm. Seizures complicate 1.5% of cases, and encephalopathy occurs in 0.1%. The encephalopathy frequently is fatal. Anoxic brain damage, cerebral hemorrhage, or pertussis neurotoxins are hypothesized, but anoxia is most likely the cause. Epistaxis and subconjunctival hemorrhages are common.

### Prevention

Active immunization (see Chapter 10) with DTaP vaccine should be given in early infancy. The occurrence and increased recognition of disease in adolescents and adults contributes to the increasing number of cases. A booster dose of vaccine in adolescents between the ages of 11 and 18 years is recommended. Subsequent booster doses of Tdap...
are recommended for adults aged 18–60 years to replace Td boosters. Immunization of pregnant women, new mothers, care givers of infants less than 6 months, and healthcare workers of young children is also recommended.

Chemoprophylaxis with azithromycin should be given to exposed family, household and hospital contacts, particularly those younger than age 2 years, although data to support the efficacy of such preventive therapy are not strong. Hospitalized children with pertussis should be isolated because of the great risk of transmission to patients and staff. Several large hospital outbreaks have been reported.

Treatment

A. Specific Measures

Antibiotics may ameliorate early infections but have no effect on clinical symptoms in the paroxysmal stage. Azithromycin is the drug of choice because it promptly terminates respiratory tract carriage of B pertussis. Resistance to macrolides has been rarely reported. Clarithromycin may also be used. Erythromycin given 4 times daily for 14 days is acceptable but not preferred. Ampicillin (100 mg/kg/d in four divided doses) may also be used for erythromycin-intolerant patients. Azithromycin is often preferred due to ease of compliance and decreased gastrointestinal side effects. Erythromycin has been associated with pyloric stenosis in infants less than 1 month of age. Azithromycin is recommended for therapy or prophylaxis in infants less than 1 month.

Corticosteroids reduce the severity of disease but may mask signs of bacterial superinfection. Albuterol (0.3–0.5 mg/kg/d in four doses) has reduced the severity of illness, but tachycardia is common when the drug is given orally, and aerosol administration may precipitate paroxysms.

B. General Measures

Nutritional support during the paroxysmal phase is important. Frequent small feedings, tube feeding, or parenteral fluid supplementation may be needed. Minimizing stimuli that trigger paroxysms is probably the best way of controlling cough. In general, cough suppressants are of little benefit.

C. Treatment of Complications

Respiratory insufficiency due to pneumonia or other pulmonary complications should be treated with oxygen and assisted ventilation if necessary. Convulsions are treated with oxygen and anticonvulsants. Bacterial pneumonia or otitis media requires additional antibiotics.

Prognosis

The prognosis for patients with pertussis has improved in recent years because of excellent nursing care, treatment of complications, attention to nutrition, and modern intensive care. However, the disease is still very serious in infants younger than age 1 year; most deaths occur in this age group. Children with encephalopathy have a poor prognosis.

McIntyre PB, Sintchenko V: The “how” of polymerase chain reaction testing for Bordetella pertussis depends on the “why.” Clin Infect Dis 2013;56(3):332 [PMID: 23087394].

Listeriosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

Early-onset neonatal disease:
- Signs of sepsis a few hours after birth in an infant born with fetal distress and hepatosplenomegaly; maternal fever.

Late-onset neonatal disease:
- Meningitis, sometimes with monocytosis in the CSF and peripheral blood.
- Onset at age 9–30 days.

General Considerations

Listeria monocytogenes is a gram-positive, non–spore-forming aerobic rod distributed widely in the animal kingdom.
and in food, dust, and soil. It causes systemic infections in newborn infants and immunosuppressed older children. In pregnant women, infection is relatively mild, with fever, aches, and chills, but is accompanied by bacteremia and sometimes results in intrauterine or perinatal infection with grave consequences for the fetus or newborn. One-fourth of cases occur in pregnant women, and 20% of their pregnancies end in stillbirth or neonatal death. Listeria is present in the stool of approximately 10% of the healthy population. Persons in contact with animals are at greater risk. Outbreaks of listeriosis have been traced to contaminated cabbage in coleslaw, soft cheese, hot dogs, luncheon meats, and milk. Listeria infections have decreased since the adoption of strict regulations for ready-to-eat foods; 821 cases were reported in 2010. A large multistate outbreak due to contaminated cantaloupe has caused more than 20 deaths in elderly and immunocompromised patients in 2011, and demonstrates the potential of this organism to cause serious illness.

Like GBS infections, Listeria infections in the newborn can be divided into early and late forms. Early infections are more common, leading to a severe congenital form of infection. Later infections are often characterized by meningitis.

Clinical Findings

A. Symptoms and Signs

In the early neonatal form, symptoms of listeriosis usually appear on the first day of life and always by the third day. Fetal distress is common, and infants frequently have signs of severe disease at birth. Respiratory distress, diarrhea, and fever occur. On examination, hepatosplenomegaly and a papular rash are found. A history of maternal fever is common. Meningitis may accompany the septic course. The late neonatal form usually occurs after age 9 days and can occur as late as 5 weeks. Meningitis is common, characterized by irritability, fever, and poor feeding.

Listeria infections are rare in older children and usually are associated with immunodeficiency. Several recent cases were associated with tumor necrosis factor-α neutralizing agents. Signs and symptoms are those of meningitis, usually with insidious onset.

B. Laboratory Findings

In all infants except those receiving white cell depressant drugs, the WBC count is elevated, with 10%–20% monocytes. When meningitis is found, the characteristic CSF cell count is high (> 500/μL) with a predominance of polymorphonuclear neutrophils in 70% of cases. Monocytes may predominate in up to 30% of cases. Gram-stained smears of CSF are usually negative, but short gram-positive rods may be seen. The chief pathologic feature in severe neonatal sepsis is miliary granulomatosis with microabscesses in liver, spleen, CNS, lung, and bowel.

Culture results are frequently positive from multiple sites, including blood from the infant and the mother.

Differential Diagnosis

Early-onset neonatal disease resembles hemolytic disease of the newborn, GBS sepsis or severe cytomegalovirus infection, rubella, or toxoplasmosis. Late-onset disease must be differentiated from meningitis due to echovirus and coxsackievirus, GBS, and gram-negative enteric bacteria.

Prevention

Immunosuppressed, pregnant, and elderly patients can decrease the risk of Listeria infection by avoiding soft cheeses, by thoroughly reheating or avoiding delicatessen and ready-to-eat foods, by avoiding raw meat and milk, and by thoroughly washing fresh vegetables.

Treatment

Ampicillin (150–300 mg/kg/d every 6 hours intravenously) is the drug of choice in most cases of listeriosis. Gentamicin (2.5 mg/kg every 8 hours intravenously) has a synergistic effect with ampicillin and should be given in serious infections and to patients with immune deficits. Vancomycin may be substituted for ampicillin when empirically treating meningitis. If ampicillin cannot be used, TMP-SMX also is effective. Cephalosporins are not effective. Treatment of severe disease should continue for at least 2 weeks; meningitis is treated 2–3 weeks.

Prognosis

In a recent outbreak of early-onset neonatal disease, the mortality rate was 27% despite aggressive and appropriate management. Meningitis in older infants has a good prognosis. In immunosuppressed children, prognosis depends to a great extent on that of the underlying illness.

TUBERCULOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- All types: positive tuberculin test in patient or members of household, suggestive chest radiograph, history of contact, and demonstration of organism by stain and culture.
- Pulmonary: fatigue, irritability, and undernutrition, with or without fever and cough.
- Glandular: chronic cervical adenitis.
- Miliary: classic snowstorm appearance of chest radiograph.
- Meningitis: fever and manifestations of meningeal irritation and increased intracranial pressure. Characteristic CSF.

General Considerations

Tuberculosis is a granulomatous disease caused by Mycobacterium tuberculosis. It is a leading cause of death throughout the world. Children younger than age 3 years are most susceptible. Lymphohematogenous dissemination through the lungs to extrapulmonary sites, including the brain and meninges, eyes, bones and joints, lymph nodes, kidneys, intestines, larynx, and skin, is more likely to occur in infants. Increased susceptibility occurs again in adolescence, particularly in girls within 2 years of menarche. Following substantial increases in disease during the 1980s, tuberculosis incidence has decreased since 1992 due to increased control measures. More than 10,465 new cases were reported in 2011; only 577 of these were in children less than 14 years old. High-risk groups include ethnic minorities, foreign-born persons, prisoners, residents of nursing homes, indigents, migrant workers, and healthcare providers. However, 50% of cases occurred in U.S.-born persons. HIV infection is an important risk factor for both development and spread of disease. Pediatric tuberculosis incidence mirrors the trends seen in adults.

Exposure to an infected adult is the most common risk factor in children. The primary complex in infancy and childhood consists of a small parenchymal lesion in any area of the lung with caseation of regional nodes and calcification. Postprimary tuberculosis in adolescents and adults commonly occurs in the apices of the lungs and is likely to cause chronic progressive cavitary pulmonary disease with less tendency for hematogenous dissemination. Mycobacterium bovis infection is clinically identical to M. tuberculosis. M. bovis may be acquired from unpasteurized dairy products obtained outside the United States.

Clinical Findings

A. Symptoms and Signs

1. Pulmonary—(See Chapter 19.)

2. Miliary—Diagnosis is usually based on the classic “snowstorm” or “millet seed” appearance of lung fields on radiograph, although early in the course of disseminated tuberculosis the chest radiograph may show no or only subtle abnormalities. Choroidal tubercles are sometimes seen on funduscopic examination. Other lesions may be present and produce osteomyelitis, arthritis, meningitis, tuberculomas of the brain, enteritis, or infection of the kidneys and liver.

3. Meningitis—Symptoms include fever, vomiting, headache, lethargy, and irritability, with signs of meningeal irritation and increased intracranial pressure, cranial nerve palsies, convulsions, and coma.

4. Lymphatic—The primary complex may be associated with a skin lesion drained by regional nodes or chronic cervical node enlargement or infection of the tonsils. Involved nodes may become fixed to the overlying skin, suppurate, and drain.

B. Laboratory Findings

The tuberculin skin test (TST; 0.1 mL of intermediate-strength purified protein derivative inoculated intradermally) is positive at 48–72 hours if there is significant induration (Table 42–3). Parental reporting of skin test results is often inaccurate. All tests should be read by professionals trained to interpret TST. False-negative results occur in malnourished patients, in those with overwhelming disease, and in 10% of children with isolated pulmonary disease. Temporary suppression of tuberculin reactivity may be seen with viral infections (eg, measles, influenza, varicella, and mumps), after live virus immunization, and during corticosteroid or other immunosuppressive drug therapy. For these reasons, a negative TST test does not exclude the diagnosis of tuberculosis. When tuberculosis is suspected in a child, household members and adult contacts (eg, teachers and caregivers) also should be tested immediately. Multiple puncture tests (tine tests) should not be used because they are associated with false-negative and false-positive reactions, and because standards for interpretation of positive results do not exist. Interferon gamma release assays (IGRAs) are approved to replace TST tests in adults and older children. These assays have much higher specificity due to less common false-positive results from nontuberculosis mycobacteria and BCG. They are done on blood obtained by venipuncture and are further advantageous in requiring only a single visit. These tests are preferred in BCG-immunized children older than 4 years.
IGRA are reported as positive, negative or indeterminate. The ESR and CRP is usually elevated in symptomatic children. Cultures of pooled early morning gastric aspirates from three successive days will yield M tuberculosis in about 40% of cases. Biopsy may be necessary to establish the diagnosis. Therapy should not be delayed in suspected cases. The CSF in tuberculous meningitis shows slight to moderate pleocytosis (50–300 WBCs/μL, predominantly lymphocytes), decreased glucose, and increased protein.

The direct detection of mycobacteria in body fluids or discharges is best done by staining specimens with auramine-rhodamine and examining them with fluorescence microscopy; this method is superior to the Ziehl-Neelsen method.

C. Imaging

Chest radiograph should be obtained in all children with suspicion of tuberculosis at any site or with a positive skin test. Segmental consolidation with some volume loss and hilar adenopathy are common findings in children. Paratracheal adenopathy is a classic presentation. Pleural effusion also occurs with primary infection. Cavities and apical disease are unusual in children but are common in adolescents and adults.

Differential Diagnosis

Pulmonary tuberculosis must be differentiated from fungal, parasitic, mycoplasmal, and bacterial pneumonias; lung abscess; foreign body aspiration; lipoid pneumonia; sarcoidosis; and mediastinal cancer. Cervical lymphadenitis is most likely due to streptococcal or staphylococcal infections. Cat-scratch fever and infection with atypical mycobacteria may need to be distinguished from tuberculous lymphadenitis. Viral meningoencephalitis, head trauma (child abuse), lead poisoning, brain abscess, acute bacterial meningitis, brain tumor, and disseminated fungal infections must be excluded in tuberculous meningitis. A positive TST or IGRA in the patient or family contacts is frequently valuable in suggesting the diagnosis of tuberculosis. A negative TST or IGRA does not exclude tuberculosis.

Prevention

A. BCG Vaccine

Bacille Calmette–Guérin (BCG) vaccines are live-attenuated strains of M bovis. Although neonatal and childhood administration of BCG is carried out in countries with a high prevalence of tuberculosis, protective efficacy varies greatly with vaccine potency and method of delivery. BCG given to infants decreases disseminated tuberculosis but does not protect against pulmonary tuberculosis later in childhood or adolescence. Because the great majority of children who have received BCG still have negative TST tests, the past history of BCG vaccination should be ignored in interpreting the skin test. In the United States, BCG vaccination is not recommended. IGRA gives negative results in patients with false-positive PPDs due to BCG.

B. Isoniazid Chemoprophylaxis

Daily administration of isoniazid (10 mg/kg/d orally; maximum 300 mg) is advised for children who are exposed by prolonged close or household contact with adolescents or adults with active disease. Isoniazid is given until 8–10 weeks after last contact. At the end of this time, a TST or IGRA test should be done, and therapy should be continued for an additional 7 months if the test is positive.

C. Other Measures

Tuberculosis in infants and young children is evidence of recent exposure to active infection in an adult, usually a family member or household contact. The source contact (index case) should be identified, isolated, and given treatment to prevent other secondary cases. Reporting cases to local health departments is essential for contact tracing. Exposed tuberculin-negative children should usually receive isoniazid chemoprophylaxis. If a repeated skin test is negative 8–10 weeks following the last exposure, isoniazid may be stopped. Routine tuberculin skin testing is not recommended for children without risk factors who reside in communities with a low incidence of tuberculosis. Children with no personal risk for tuberculosis but who reside in communities with a high incidence of tuberculosis should be given a skin test at school entry and then again at age 11–16 years. Children with a risk factor for acquiring tuberculosis should be tested every 2–3 years. Incarcerated adolescents and children living in a household with HIV-infected persons should have annual skin tests.

Children who immigrate into the United States from a country with a high incidence of infection should receive TST or IGRA on entry to the United States or upon presentation to healthcare providers. A past history of BCG vaccine should not delay testing.

Treatment

A. Specific Measures

Most children with suspected active tuberculosis in the United States are hospitalized initially. If the infecting organism has not been isolated from the presumed source, reasonable attempts should be made to obtain it from the child using morning gastric aspirates, sputum, bronchoscopy, thoracentesis, or biopsy when appropriate. Unfortunately, cultures are frequently negative in children,
and the risk of these procedures must be weighed against the yield.

Therapy is given daily for 14 days and then reduced to two to three times per week for the duration of the course. Directly observed administration of all doses of antituberculosis therapy by a trained healthcare professional is essential to ensure compliance with therapy.

Children with positive skin tests (see Table 42–3) without symptoms and a normal chest radiograph have latent tuberculosis and should receive 9 months of isoniazid (10 mg/kg/d orally; maximum 300 mg) therapy. Rifampin (10–15 mg/kg/d orally; maximum 600 mg) for 4 months is efficacious and compliance is easier with the shorter duration of therapy. A combination of isoniazid and rifapentine given once per week for 12 weeks is effective in adolescents older than 12 years and adults. In children with active pulmonary disease, therapy for 6 months using isoniazid (10 mg/kg/d), rifampin (15 mg/kg/d), and pyrazinamide (25–30 mg/kg/d) in a single daily oral dose for 2 months, followed by isoniazid plus rifampin (either in a daily or twice-weekly regimen) for 4 months appears effective for eliminating isoniazid-susceptible organisms. For more severe disease, such as miliary or CNS infection, duration is increased to 12 months or more, and a fourth drug (streptomycin or ethambutol) is added for the first 2 months. In communities with resistance rates greater than 4%, initial therapy should usually include four drugs.

1. Isoniazid—The hepatotoxicity from isoniazid seen in adults and some adolescents is rare in children. Transient elevation of aminotransferases (up to three times normal) may be seen at 6–12 weeks, but therapy is continued unless clinical illness occurs. Routine monitoring of liver function tests is unnecessary unless prior hepatic disease is known or the child is severely ill. Peripheral neuropathy associated with pyridoxine deficiency is rare in children, and it is not necessary to add pyridoxine unless significant malnutrition coexists or if the child is strictly breastfed.

2. Rifampin—Although it is an excellent bactericidal agent, rifampin is never used alone to treat active disease, owing to rapid development of resistance. Hepatotoxicity may occur but rarely with recommended doses. Rifampin causes an orange color of urine and secretions which is benign but may stain contact lenses or clothes. Rifampin interacts with many medications including anticonvulsants, some seizure medications, birth control pills, and Coumadin.

3. Pyrazinamide—This excellent sterilizing agent is most effective during the first 2 months of therapy. With the recommended duration and dosing, it is well tolerated. Although pyrazinamide elevates the uric acid level, it rarely causes symptoms of hyperuricemia in children. Use of this drug is now common for tuberculous disease in children, and resistance is uncommon. Oral acceptance and CNS penetration are good.

4. Ethambutol—Because optic neuritis is the major side effect in adults, ethambutol has usually been given only to children whose vision can be reliably tested for loss of color differentiation. Optic neuritis is rare and usually occurs in adults receiving more than the recommended dosage of 25 mg/kg/d. Documentation of optic toxicity in children is lacking despite considerable worldwide experience. Therefore, many four-drug regimens for children now include ethambutol.

5. Streptomycin—Streptomycin (20–30 mg/kg/d, given intramuscularly in one or two doses) should be given for 1 or 2 months in severe disease. The child’s hearing should be tested periodically during use as ototoxicity is common.

B. Chemotherapy for Drug-Resistant Tuberculosis

The incidence of drug resistance is increasing and reaches 10%–20% in some areas of the United States. Transmission of multiple drug-resistant and extensively drug-resistant strains to contacts has occurred in some epidemics. Consultation with local experts in treating tuberculosis is important in these difficult cases. Therapy should continue for 18 months or longer. Often, four to six first- and second-line medications are needed.

C. General Measures

Corticosteroids may be used for suppressing inflammatory reactions in meningeal, pleural, and pericardial tuberculosis and for the relief of bronchial obstruction due to hilar adenopathy. Prednisone is given orally, 1 mg/kg/d for 2 weeks, with gradual withdrawal over the next 4–6 weeks. The use of corticosteroids may mask progression of disease. Accordingly, the clinician needs to be sure that an effective regimen is being used.

Prognosis

If bacteria are sensitive and treatment is completed, most children are cured with minimal sequelae. Repeat treatment is more difficult and less successful. With antituberculosis chemotherapy (especially isoniazid), there should now be nearly 100% recovery in miliary tuberculosis. Without treatment, the mortality rate in both miliary tuberculosis and tuberculous meningitis is almost 100%. In the latter form, about two-thirds of patients receiving treatment survive. There may be a high incidence of neurologic abnormalities among survivors if treatment is started late.
Chronic unilateral cervical lymphadenitis.

Granulomas of the skin.

Chronic bone lesion with draining sinus (chronic osteomyelitis).

Reaction to PPD-S (standard) of 5–8 mm, negative chest radiograph, and negative history of contact with tuberculosis.

Diagnosis by positive acid-fast stain or culture.

Disseminated infection in patients with AIDS.

General Considerations

Many species of acid-fast mycobacteria other than *M. tuberculosis* may cause subclinical infections and occasionally clinical disease resembling tuberculosis. Strains of nontuberculous mycobacteria are common in soil, food, and water. Organisms enter the host by small abrasions in skin, oral mucosa, or gastrointestinal mucosa. Strain cross-reactivity with *M. tuberculosis* can be demonstrated by simultaneous skin testing (Mantoux) with PPD-S (standard) and PPD prepared from one of the atypical antigens. Unfortunately, reagents prepared for routine nontuberculosis skin testing are not available to clinicians.

*Mycobacterium avium* complex (MAC), *Mycobacterium kansasii*, *Mycobacterium fortuitum*, *Mycobacterium abscessus*, *Mycobacterium marinum*, and *Mycobacterium chelonae* are most commonly encountered. *M. fortuitum*, *M. abscessus*, and *M. chelonae* are “rapid growers” requiring 3–7 days for recovery, whereas other mycobacteria require several weeks. After inoculation they form colonies closely resembling *M. tuberculosis* morphologically.

Clinical Findings

A. Symptoms and Signs

1. Lymphadenitis—In children, the most common form of infection due to mycobacteria other than *M. tuberculosis* is cervical lymphadenitis. MAC is the most common organism. A submandibular or cervical node swells slowly and is firm and initially somewhat tender. Low-grade fever may occur. Over time, the node suppurates and may drain chronically. Nodes in other areas of the head and neck elsewhere are sometimes involved.

2. Pulmonary disease—In the western United States, pulmonary disease is usually due to *M. kansasii*. In the eastern United States, it may be due to MAC. In other countries, disease is usually caused by MAC. In adults, there is usually underlying chronic pulmonary disease. Immunologic deficiency may be present. Presentation is clinically indistinguishable from that of tuberculosis. Adolescents with cystic fibrosis may be infected with nontuberculous mycobacteria.

3. Swimming pool granuloma—This is due to *M. marinum*. A solitary chronic granulomatous lesion with satellite lesions develops after minor trauma in infected swimming pools or other aquatic sources. Minor trauma in home aquariums or other aquatic environments may also lead to infection.

4. Chronic osteomyelitis—Osteomyelitis is caused by *M. kansasii*, *M. fortuitum*, or other rapid growers. Findings include swelling and pain over a distal extremity, radiolucent defects in bone, fever, and clinical and radiographic evidence of bronchopneumonia. Such cases are rare.

5. Meningitis—Disease is due to *M. kansasii* and may be indistinguishable from tuberculous meningitis.

6. Disseminated infection—Rarely, apparently immunologically normal children develop disseminated infection due to nontuberculous mycobacteria. Children are ill, with fever and hepatosplenomegaly, and organisms are demonstrated in bone lesions, lymph nodes, or liver. Chest radiographs are
INFECTIONS: BACTERIAL & SPIROCHETAL

usually normal. Between 60% and 80% of patients with AIDS will acquire MAC infection, characterized by fever, night sweats, weight loss, and diarrhea. Infection usually indicates severe immune dysfunction and is associated with CD4 lymphocyte counts less than 50/μL.

B. Laboratory Findings

In most cases, there is a small reaction (< 10 mm) when Mantoux testing is done. Larger reactions may be seen particularly with *M. marinum* infection. The chest radiograph is negative, and there is no history of contact with a case of tuberculosis. Needle aspiration of the node excludes bacterial infection and may yield acid-fast bacilli on stain or culture. Fistulization should not be a problem because total excision is usually recommended for infection due to atypical mycobacteria. Cultures of any normally sterile body site may yield MAC in immunocompromised patients with disseminated disease. Blood cultures are positive, with a large density of bacteria.

Differential Diagnosis

See section on differential diagnosis in the previous discussion of tuberculosis and in Chapter 19.

Treatment

A. Specific Measures

The usual treatment of lymphadenitis is complete surgical excision. Occasionally excision is impossible because of proximity to branches of the facial or other nerves or the salivary glands. Chemotherapy may then be necessary. Response of extensive adenopathy or other forms of infection varies according to the infecting species and susceptibility. Usually, combinations of two to four medications administered for months are required. Isoniazid, rifampin, and ethambutol (depending on sensitivity to isoniazid) will result in a favorable response in almost all patients with *M. kansasii* infection. Chemotherapeutic treatment of MAC is much less satisfactory because resistance to isoniazid, rifampin, and pyrazinamide is common. Susceptibility testing is necessary to optimize therapy. Most clinicians favor surgical excision of involved tissue if possible and treatment with at least three drugs to which the organism has been shown to be sensitive. Disseminated disease in patients with AIDS calls for a combination of three or more active drugs. Clarithromycin or azithromycin and ethambutol is started, in addition to one or more of the following drugs: ethionamide, capreomycin, amikacin, rifabutin, rifampin or ciprofloxacin. *M. fortuitum* and *M. chelonae* are usually susceptible to amikacin plus cefoxitin or meropenem followed by clarithromycin, azithromycin, or doxycycline, and may be successfully treated with such combinations. Swimming pool granuloma due to *M. marinum* is usually treated with doxycycline (in children older than 9 years) or rifampin, plus ethambutol, clarithromycin, or TMP-SMX for a minimum of 3 months. Surgery may also be beneficial.

B. Chemoprophylaxis

Children with HIV are given chemoprophylaxis with azithromycin or clarithromycin to prevent disseminated MAC infection. Chemoprophylaxis is given when CD4+ T-lymphocyte counts fall below age specific levels.

C. General Measures

Isolation of the patient is usually not necessary. General supportive care is indicated for the child with disseminated disease.

Prognosis

The prognosis is good for patients with localized disease, although fatalities occur in immunocompromised patients with disseminated disease.

Centers for Disease Control and Prevention (CDC): *Mycobacterium avium* complex. Available at: www.cdc.gov/ncidod/dbmd/diseaseinfo/mycobacteriumavium_t.htm

LEGIONELLA INFECTION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Severe progressive pneumonia in a child with compromised immunity.
- Diarrhea and neurologic signs are common.
- Positive culture requires buffered charcoal yeast extract media and proves infection.
- Direct fluorescent antibody staining of respiratory secretions and urinary antigen tests are highly specific but do not identify all infections.
General Considerations

*Legionella pneumophila* is a ubiquitous gram-negative bacillus that causes two distinct clinical syndromes: Legionnaires disease and Pontiac fever. Over 40 species of Legionella have been discovered, but not all cause disease in humans. *L. pneumophila* causes most infections. Legionella is present in many natural water sources as well as domestic water supplies (faucets and showers), and fountains. Contaminated cooling towers and heat exchangers have been implicated in several large institutional outbreaks. Person-to-person transmission has not been documented.

Few cases of Legionnaires disease have been reported in children. Most were in children with compromised cellular immunity. In adults, risk factors include smoking, underlying cardiopulmonary or renal disease, alcoholism, and diabetes.

*L. pneumophila* is thought to be acquired by inhalation of a contaminated aerosol. The bacteria are phagocytosed but proliferate within macrophages. Cell-mediated immunity is necessary to activate macrophages to kill intracellular bacteria.

Prevention

No vaccine is available. Legionella is naturally found in water, so ensuring proper disinfectant and water temperature maintenance of water supplies will help prevent cases. Good cleaning, attention to pH, and proper disinfectants in hot tubs is important. Chlorine or monochloramine treatment of municipal water supplies has been shown to reduce the number of organisms and the risk of infection.

Clinical Findings

A. Symptoms and Signs

In Legionnaires disease there is an abrupt onset of fever, chills, anorexia, and headache. Pulmonary symptoms appear within 2–3 days and progress rapidly. The cough is non-productive early. Purulent sputum occurs late. Hemoptysis, diarrhea, and neurologic signs (including lethargy, irritability, tremors, and delirium) are seen.

B. Laboratory Findings

The WBC count is usually elevated in Legionnaires disease. Chest radiographs show rapidly progressive patchy consolidation. Cavitation and large pleural effusions are uncommon. Cultures from sputum, tracheal aspirates, or bronchoscopic specimens, when grown on specialized media are positive in 70%–80% of patients at 3–5 days. Direct fluorescent antibody staining of sputum or tracheal secretions does not rule out disease due to Legionella. PCR detection of respiratory secretions for Legionella is available at some centers. Urine antigen tests for Legionella antigen are highly specific. These tests only detect *L. pneumophila* serotype 1, but most community-acquired *L. pneumophila* infections are caused by this serotype. Performance of both culture and urine antigen testing should facilitate diagnosis. Serologic tests are available, but a maximum rise in titer may require 6–8 weeks.

Differential Diagnosis

Legionnaires disease is usually a rapidly progressive pneumonia in a patient who appears very ill with unremitting fevers. Other bacterial pneumonias, viral pneumonias, *Mycoplasma* pneumonia, and fungal disease are all possibilities and may be difficult to differentiate clinically in an immunocompromised patient.

Complications

In sporadic untreated cases, mortality rates are 5%–25%. The mortality rate is < 5% in normal hosts with early, appropriate therapy. In immunocompromised patients with untreated disease, mortality approaches 80%. Hematogenous dissemination may result in extrapulmonary foci of infection, including pericardium, myocardium, and kidneys. Legionella may be the cause of culture-negative endocarditis.

Treatment

Intravenous azithromycin, 10 mg/kg/d given as a once-daily dose (maximum dose 500 mg), is the drug of choice in most children. In immunocompromised patients, levofloxacin is recommended (not approved for this indication in children < 18 years of age) because fluoroquinolones are cidal agents. Fluoroquinolones are not approved for use, doxycycline (not recommended for children < 8 years of age unless benefit exceeds risk) and TMP-SMX are alternative agents. Duration of therapy is 5–10 days if azithromycin is used; for other antibiotics a 14- to 21-day course is recommended. Oral therapy may be substituted for intravenous therapy as the patient’s condition improves.

Prognosis

Mortality rate is high if treatment is delayed. Malaise, problems with memory, and fatigue are common after recovery.

Centers for Disease Control and Prevention: Legionella. Available at: http://www.cdc.gov/legionella/
**CHLAMYDOPHILA INFECTIONS (PSITTACOSIS [ORNITHOSIS], C PNEUMONIAE & C TRACHOMATIS)**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- **Psittacosis:**
  - Fever, cough, malaise, chills, headache.
  - Diffuse rales; no consolidation.
  - Long-lasting radiographic findings of bronchopneumonia.
  - Isolation of the organism or rising titer of complement fixing antibodies.
  - Exposure to infected birds (ornithosis).
- **Neonatal Chlamydia (Chlamydia) conjunctivitis:**
  - Watery, mucopurulent, to blood tinged discharge and conjunctival injection presenting from a few days of life until 16 weeks of age.
  - May be associated with neonatal Chlamydia pneumonia.
  - Identification of Chlamydia conjunctivitis or pneumonia in a neonate should prompt evaluation and treatment of the mother and her sexual partner.

**General Considerations**

Psittacosis is caused by Chlamyphila psittaci. When the agent is transmitted to humans from psittacine birds (parrots, parakeets, cockatoos, and budgerigars), the disease is called psittacosis or parrot fever. However, other avian genera (eg, pigeons and turkeys) are common sources of infection in the United States, and the general term ornithosis is used. The agent is an obligate intracellular parasite. Human-to-human spread rarely occurs. The incubation period is 5–14 days. The bird from which the disease was transmitted may not be clinically ill.

Chlamydia pneumoniae (formerly Chlamydia pneumoniae) may cause atypical pneumonia similar to that due to M pneumoniae. Transmission is by respiratory spread. Infection appears to be most prevalent during the second decade; half of surveyed adults are seropositive. Only a small percentage of infections result in clinical pneumonia. Lower respiratory tract infection due to C pneumoniae is uncommon in infants and young children. C pneumoniae has been associated with acute chest syndrome in children with sickle cell disease.

Chlamydia pneumoniae causes urogenital infections in adults including asymptomatic infections, lymphogranuloma venereum, nongonococcal urethritis, epididymitis, cervicitis, and pelvic inflammatory disease. Serovars D–K (and L1, L2, L3 in lymphogranuloma venereum) are responsible for most of these infections. In infants born to infected mothers, C trachomatis infection can be acquired through exposure in the birth canal, causing neonatal conjunctivitis and/or pneumonia. The risk of acquisition for a baby born vaginally to an infected mother is about 50%.

The disease called “trachoma” is unusual in the United States. Trachoma is caused by certain C trachomatis serovars (A–C). This chronic keratoconjunctivitis can cause inflammation and neovascularization of the cornea, leading to corneal scarring and blindness. It is the most common cause of acquired blindness worldwide. The peak incidence is seen at age 4–6, with scarring and blindness occurring in adulthood. Infections occur from direct contact with infected secretions (eye, nose, throat) or by direct contact with contaminated objects (secretions on towels, washcloths, handkerchiefs).

Sexually transmitted urogenital infections caused by Chlamydia are discussed in Chapter 44.

**Prevention**

Persons cleaning bird cages should use caution when cleaning cages or disposing of bird droppings to avoid aerosolization of C psittaci. C psittaci is susceptible to 1% Lysol or a 1:100 dilution of household bleach and one of these can be used to disinfect cages. Sick birds should be evaluated by a veterinarian and can be treated with antimicrobials. C pneumoniae is transmitted person to person by infected respiratory tract secretions. Prevention involves avoidance of known infected persons, using good hand hygiene (both infected persons and noninfected persons), and encouraging good respiratory hygiene (covering mouth with coughing, disposing of tissues contaminated with respiratory secretions).

The diagnosis and appropriate treatment of genital Chlamydia (chlamydial) infections in pregnant women and their sexual partners is the most effective way to prevent neonatal conjunctivitis and pneumonia (see Chapter 44).

**Clinical Findings**

**A. Symptoms and Signs**

1. **C psittaci pneumonia**—The disease is extremely variable but tends to be mild in children. The onset is rapid or insidious, with fever, chills, headache, backache, malaise, myalgia, and dry cough. Signs include pneumonitis, altered percussion notes and breath sounds, and rales. Pulmonary findings may be absent early. Dypsnea and cyanosis may occur later. Splenomegaly, epistaxis, prostration, and meningismus are occasionally seen. Delirium, constipation or diarrhea, and abdominal distress may occur.
2. *C. pneumoniae* pneumonia—Clinically, *C. pneumoniae* infection is similar to *M. pneumoniae* infection. Most patients have mild upper respiratory infections. Lower respiratory tract infection is characterized by fever, sore throat (perhaps more severe with *C. pneumoniae*), cough, and bilateral pulmonary findings and infiltrates.

3. *C. trachomatis* neonatal conjunctivitis and pneumonia—Neonatal conjunctivitis caused by *C. trachomatis* can occur from a few days until 12–16 weeks after birth. There may be mild to moderate swelling of the lids and watery or mucopurulent discharge. The conjunctivae may be friable and there may be some bloody discharge. Pneumonia may occur in babies with or without neonatal conjunctivitis. Pneumonia is most commonly seen between 2 and 12 weeks of age. Most babies are afebrile and have tachypnea and a staccato cough.

4. *C. trachomatis* trachoma—Trachoma is unusual in the United States. It is seen in developing countries in Africa, Asia, Latin America, the Middle East, and some Pacific and East Pacific islands. This chronic keratoconjunctivitis can cause inflammation and neovascularization of the cornea, leading to corneal scarring and blindness. It is the most common cause of acquired blindness worldwide. The peak incidence is seen at 4–6 years of age, with scarring and blindness occurring in adulthood. Infections occur from direct contact with infected secretions (eye, nose, throat) or by direct contact with contaminated objects (secretions on towels, washcloths, handkerchiefs). Trachoma is caused by certain *C. trachomatis* serovars (A–C).

B. Laboratory Findings

1. *C. psittaci*—In psittacosis, the WBC count is normal or decreased, often with a shift to the left. Proteinuria is common. *C. psittaci* is present in the blood and sputum during the first 2 weeks of illness but culture is avoided since it can represent a hazard to laboratory workers. A diagnosis can be made if, a culture (blood or respiratory tract specimen) is positive for the organism, or there is a fourfold rise in complement fixation titers in specimens obtained at least 2 weeks apart. Evidence of a probable case includes those where there is a single serum *C. psittaci* IgM antibody titer above 1:32 (microimmunofluorescent or complement fixation assay). The titer rise may be blunted or delayed by therapy. Infection with *C. pneumoniae* may lead to diagnostic confusion because cross-reactive antibody may cause false-positive *C. psittaci* titers.

2. *C. pneumoniae*—Eosinophilia is sometimes present. A fourfold rise in *C. pneumoniae* IgG titer (microimmunofluorescence antibody test). IgG antibody peaks 6–8 weeks after infection. *C. pneumoniae* can be isolated from nasal wash or throat swab specimens after inoculation into cell culture. A PCR is currently not commercially available.

3. *C. trachomatis*—In infants with neonatal pneumonia or conjunctivitis, nucleic acid amplification tests (such as PCR) have not been FDA approved for testing conjunctival samples or respiratory samples (nasopharyngeal, tracheal aspirate) in infants. Culture or nonamplified direct detection methods are usually utilized.

C. Imaging

The radiographic findings in psittacosis are those of central pneumonia that later becomes widespread or migratory. Psittacosis is indistinguishable from viral pneumonias by radiograph. Signs of pneumonitis may appear on radiograph in the absence of clinical suspicion of pulmonary involvement.

In neonatal pneumonia from *C. trachomatis*, infiltrates, and often hyperinflation, are seen on chest radiographs.

**Differential Diagnosis**

Psittacosis can be differentiated from viral or mycoplasmal pneumonias only by the history of contact with potentially infected birds. In severe or prolonged cases with extrapulmonary involvement the differential diagnosis is broad, including typhoid fever, brucellosis, and rheumatic fever.

*C. pneumoniae* pneumonia is not distinguishable clinically from *Mycoplasma* or viral pneumonia. *C. trachomatis* conjunctivitis must be differentiated from gonococcal conjunctivitis, chemical conjunctivitis, or viral conjunctivitis. Gonococcal conjunctivitis is often severe, with purulent discharge. A culture of the conjunctival discharge (plated on Thayer-Martin media) can aid in the diagnosis of gonococcal conjunctivitis.

**Complications**

Complications of psittacosis include myocarditis, endocarditis, hepatitis, pancreatitis, and secondary bacterial pneumonia. *C. pneumoniae* infection may be prolonged or may recur.

**Treatment**

Psittacosis—Doxycycline should be given for 10–14 days after defervescence to patients older than 8 years with psittacosis. Alternatively, erythromycin or azithromycin may be used in younger children. Supportive oxygen may be needed.

*Chlamydia pneumoniae*—Most suspected infections are treated empirically. *C. pneumoniae* responds to macrolides (azithromycin, erythromycin). Doxycycline is an alternative in those patients 8 years and older. A 10- to 14-day course is recommended for erythromycin or doxycycline; when using azithromycin the treatment length is 5 days.

Neonatal conjunctivitis or pneumonia—The American Academy of Pediatrics recommends a 10-day course of erythromycin base or ethylsuccinate (50 mg/kg/d given in four divided doses). Infants should have a follow-up visit
because some infants have recrudescence of symptoms after the antibiotic course finishes or failure of symptoms to fully resolve. These infants can be retreated with a second course of erythromycin. Data on the use of azithromycin for these conditions in neonates is very limited, but azithromycin 20 mg/kg, given as an oral single dose once daily for 3 days, may be efficacious. An association with receipt of erythromycin and development of pyloric stenosis in infants less than 6 weeks of age has been reported. Parents should be informed of this potential risk and the symptoms of pyloric stenosis. There are case reports of pyloric stenosis occurring in infants who previously received azithromycin. The diagnosis of an infant with chlamydial conjunctivitis and/or pneumonia should prompt evaluation and treatment of the mother and her sexual partner for Chlamydia and other sexually transmitted diseases (see Chapter 44).

Centers for Disease Control and Prevention: Chlamydia pneumoniae. Available at: http://www.cdc.gov/ncidod/dbmd/diseaseinfo/chlamydiapneumonia_t.htm

## CAT-SCRATCH DISEASE

### ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- History of a cat scratch or cat contact.
- Primary lesion (papule, pustule, or conjunctivitis) at site of inoculation.
- Acute or subacute regional lymphadenopathy.
- Aspiration of sterile pus from a node.
- Laboratory studies excluding other causes.
- Biopsy of node or papule showing histopathologic findings consistent with cat-scratch disease and occasionally characteristic bacilli on Warthin-Starry stain.
- Positive cat-scratch serology (antibody to *Bartonella henselae*).

### General Considerations

The causative agent of cat-scratch disease is *B henselae*, a gram-negative bacillus that also causes bacillary angiomatosis. Cat-scratch disease is usually a benign, self-limited form of lymphadenitis. Patients often report a cat scratch (67%), bite (less common), or contact with a cat or kitten (90%). The cat almost invariably is healthy. Cats become infected via an infected flea; the flea becomes infected when feeding on a cat that is bacteremic with *B henselae*. Occasionally dogs can be infected and transmit disease. The clinical picture is that of a regional lymphadenitis associated with an erythematous papular skin lesion without intervening lymphangitis. The disease occurs worldwide and is more common in the fall and winter. It is estimated that more than 20,000 cases per year occur in the United States. The most common systemic complication is encephalitis.

### Prevention

Cat-scratch disease can be largely prevented by avoiding contact with cats, especially kittens. Flea control of animals will reduce cat-to-cat transmission.

### Clinical Findings

#### A. Symptoms and Signs

About 50% of patients with cat-scratch disease develop a primary lesion at the site of the wound. The lesion usually is a papule or pustule that appears 7–10 days after injury and is located most often on the arm or hand (50%), head or leg (30%), or trunk or neck (10%). The lesion may be conjunctival (10%). Regional lymphadenopathy appears 10–50 days later and may be accompanied by mild malaise, lassitude, headache, and fever. Multiple sites are seen in about 10% of cases. Involved nodes may be hard or soft and 1–6 cm in diameter. They are usually tender, warm, and erythematous and 10%–20% of them suppurate. Lymphadenopathy usually resolves in about 2 months but may persist for up to 8 months.

Unusual manifestations include erythema nodosum, thrombocytopenic purpura, conjunctivitis (Parinaud ocu-loglandular fever), parotid swelling, pneumonia, osteolytic lesions, mesenteric and mediastinal adenitis, neuroretinitis, peripheral neuritis, hepatitis, granulomata of the liver and spleen, and encephalopathy.

Immunocompetent patients may develop an atypical systemic form of cat-scratch disease. These patients have prolonged fever, fatigue, and malaise. Lymphadenopathy may be present. Hepatosplenomegaly or low-density hepatic or splenic lesions visualized by ultrasound or computed tomography scan are seen in some patients.

Infection in immunocompromised individuals may take the form of bacillary angiomatosis, presenting as vascular tumors of the skin and subcutaneous tissues. Immunocompromised patients may also have bacteremia or infection of the liver (peliosis hepatis).
B. Laboratory Findings

Serologic evidence of Bartonella infection by indirect immunofluorescent antibody with IgG titer of > 1:256 is strongly suggestive of recent infection. A positive IgM antibody is sometimes positive, the diagnosis. PCR assays are available. Cat-scratch skin test antigens are not recommended.

Histopathologic examination of involved tissue may show pyogenic granulomas or bacillary forms demonstrated by Warthin-Starry silver stain (but bacillary forms on stain are not specific for cat scratch disease). Later in the course necrotizing granulomas may be seen. There usually is some elevation in the ESR. In patients with CNS involvement, the CSF is usually normal but may show a slight pleocytosis and modest elevation of protein.

Differential Diagnosis

Cat-scratch disease must be distinguished from pyogenic adenitis, tuberculosis (typical and atypical), tularemia, plague, brucellosis, lymphoma, primary toxoplasmosis, infectious mononucleosis, lymphogranuloma venereum, and fungal infections.

Treatment

Treatment of cat-scratch disease adenopathy is controversial because the disease usually resolves without therapy and the patient is typically not exceedingly ill. Treatment of typical cat-scratch disease with a 5-day course of azithromycin has been shown to speed resolution of lymphadenopathy in some patients. The best therapy is reassurance that the adenopathy is benign and will subside spontaneously with time (mean duration of illness is 14 weeks). In cases of nodal suppuration, needle aspiration under local anesthesia relieves the pain. Excision of the involved node is indicated in cases of chronic adenitis. In some reports, azithromycin, ciprofloxacin, rifampin, or TMP-SMX have been useful. Azithromycin is used by many experts if treatment of adenopathy is desired because it is given once a day, is reasonably priced, and was studied in one randomized placebo-controlled trial. In that trial, lymph node volume decreased faster than placebo by 1 month; there was no difference in long-term resolution in the azithromycin and placebo groups.

Immunocompromised patients with evidence of infection should be treated with antibiotics: long-term therapy (months) in these patients with azithromycin or doxycycline often is needed to prevent relapses. Immunocompetent patients with more severe disease or evidence of systemic infection (eg, hepatic or splenic lesions) should also be treated with antibiotics.

Prognosis

The prognosis is good if complications do not occur.

SYPHILIS

Essentials of Diagnosis & Typical Features

Congenital:  
- All types: history of untreated maternal syphilis, a positive serologic test, and a positive darkfield examination.  
- Newborn: hepatosplenomegaly, characteristic radiographic bone changes, anemia, increased nucleated red cells, thrombocytopenia, abnormal spinal fluid, jaundice, edema.  
- Young infant (3–12 weeks): snuffles, maculopapular skin rash, mucocutaneous lesions, pseudoparalysis (in addition to radiographic bone changes).  
- Children: stigmata of early congenital syphilis, interstitial keratitis, saber shins, gummas of nose and palate.

Acquired:  
- Chancre of genitals, lip, or anus in child or adolescent.  
- History of sexual contact.

General Considerations

Syphilis is a chronic, generalized infectious disease caused by a spirochete, Treponema pallidum. In the acquired form, the disease is transmitted by sexual contact. Primary syphilis is characterized by the presence of an indurated painless chancre, which heals in 7–10 days. A secondary eruption involving the skin and mucous membranes appears in 4–6 weeks. After a long latency period, late lesions of tertiary syphilis involve the eyes, skin, bones, viscera, CNS, and cardiovascular system.

Congenital syphilis results from transplacental infection. Infection may result in stillbirth or produce illness in the newborn, in early infancy, or later in childhood. Syphilis occurring in the newborn and young infant is comparable to secondary disease in the adult but is more severe and life-threatening. Late congenital syphilis (developing in childhood) is comparable to tertiary disease.
The incidence of primary and secondary syphilis is increasing in the United States particularly among men. Nearly, 14,000 new cases of primary and secondary syphilis, 377 cases of congenital syphilis and nearly 45,000 total cases were reported in 2010.

## Prevention

A serologic test for syphilis should be performed at the initiation of prenatal care and repeated at delivery in women at increased risk for syphilis. Serologic tests may be negative on both the mother and infant at the time of birth if the mother acquires syphilis near term. Adequate treatment of mothers with secondary syphilis before the last month of pregnancy reduces the incidence of congenital syphilis from 90% to less than 2%. Examination and serologic testing of sexual partners and siblings should also be done.

## Clinical Findings

### A. Symptoms and Signs

#### 1. Congenital Syphilis

**A. Newborns**—Most newborns with congenital syphilis are asymptomatic. If infection is not detected and treated, symptoms develop within weeks to months. When clinical signs are present, they usually consist of jaundice, anemia with or without thrombocytopenia, increase in nucleated red blood cells, hepatosplenomegaly, and edema. Overt signs of meningitis (bulging fontanelle or opisthotonos) may be present, but subclinical infection with CSF abnormalities is more common.

**B. Young infants (3–12 weeks)**—The infant may appear normal for the first few weeks of life only to develop mucocutaneous lesions and pseudoparalysis of the arms or legs. Shotty lymphadenopathy may be felt. Hepatomegaly is universal, with splenomegaly in 50% of patients. Other signs of disease similar to those seen in the newborn may be present. Anemia has been reported as the only presenting manifestation of congenital syphilis in this age group. “Snuffles” (syphilitic rhinitis), characterized by a profuse runny nose, and a high forehead (secondary to mild hydrocephalus associated with low-grade meningitis and frontal periostitis). The permanent upper central incisors may be peg-shaped with a central notch (Hutchinson teeth), and the cusps of the sixth-year molars may have a lobulated mulberry appearance.

#### C. Children—Bilateral interstitial keratitis (at age 6–12 years) is characterized by photophobia, increased lacrimation, and vascularization of the cornea associated with exudation. Chorioretinitis and optic atrophy may also be seen. Meningovascular syphilis (at age 2–10 years) is usually slowly progressive, with mental retardation, spasticity, abnormal pupillary response, speech defects, and abnormal CSF. Deafness sometimes occurs. Thickening of the periosteum of the anterior tibias produces saber shins. A bilateral effusion in the knee joints may occur but is not associated with sequelae. Soft inflammatory growths called gummas may develop in the nasal septum, palate, long bones, and subcutaneous tissues.

#### 2. Acquired syphilis—The primary chancre of the genitals, mouth, or anus may occur from genital, anal, or oral sexual contact. If the chancre is missed, signs of secondary syphilis, such as rash, fever, headache, and malaise, may be the first manifestations.

### B. Laboratory Findings

#### 1. Darkfield microscopy—Treponemes can be seen in scrapings from a chancre and from moist lesions.

#### 2. Serologic tests for syphilis—There are two general types of serologic tests for syphilis: treponemal and nontreponemal. There are two types of nontreponemal tests: Venereal Disease Research Laboratory (VDRL) and the rapid plasma reagin (RPR). The VDRL and RPR are inexpensive, rapid tests that are useful for screening and following disease activity or adequacy of therapy. These tests provide quantitative results if the test is positive. False-positive nontreponemal tests can occur in patient with measles, hepatitis, mononucleosis, lymphoma, tuberculosis, endocarditis, pregnancy, and intravenous drug abuse. When evaluating a newborn infant for potential syphilis, umbilical cord blood specimens should not be used for nontreponemal tests: a false-positive test may result from Wharton jelly contamination of the sample. Conversely, a false-negative test may be seen in the setting where maternal infection occurred late in pregnancy.

Positive nontreponemal tests should be confirmed with a more specific treponemal test such as the fluorescent treponemal antibody absorbed (FTA-ABS) test or the T pallidum particle agglutination (TP-PA) test. False-positive FTA-ABS tests are uncommon except with other spirochetal diseases such as leptospirosis, rat bite fever, and Lyme disease.

One or two weeks after the onset of primary syphilis (chancre), the FTA-ABS test becomes positive. The VDRL or a similar nontreponemal test usually turns positive a few days later. By the time the secondary stage has been reached, virtually all patients show both positive FTA-ABS and positive nontreponemal tests. During latent and tertiary syphilis,
the VDRL may become negative, but the FTA-ABS test usually remains positive. The quantitative VDRL or a similar nontreponemal test should be used to follow-up treated cases (see following discussion).

EIA tests specific for *T pallidum* are available in many laboratories and are replacing FTA-ABS, TP-PA tests. As these are rapid, inexpensive tests with greater specificity, a different screening strategy is now often used. The initial screen is done with EIA test followed by the RPR or VDRL, if positive.

In infants, positive serologic tests in cord sera may represent passively transferred antibody rather than congenital infection and therefore must be supplemented by a combination of clinical and laboratory data. Elevated total cord IgM is a helpful but nonspecific finding. A specific IgM–FTA-ABS is available, but negative results are not conclusive and should not be relied on. Demonstration of characteristic treponemes by darkfield examination of material from a moist lesion (skin; nasal or other mucous membranes) is definitive. Mouth lesions would be best examined by direct fluorescent antibody to distinguish *T pallidum* from nonpathogenic treponemes commonly found in the mouth. Serial measurement of quantitative RPR or VDRL is also very useful, because passively transferred antibody in the absence of active infection should decay with a normal half-life of about 18 days (see discussion of evaluation of infants for congenital syphilis section on Initial Evaluation and Treatment).

For evaluation of possible neurosyphilis, the CSF should be examined for cell count, glucose, protein, and a CSF VDRL. A negative CSF VDRL does not rule out neurosyphilis.

C. Imaging

Radiographic abnormalities are present in 90% of infants with symptoms of congenital syphilis and in 20% of asymptomatic infants. Metaphyseal lucent bands, periostitis, and a widened zone of provisional calcification may be present. Bilateral symmetrical osteomyelitis with pathologic fractures of the medial tibial metaphyses (Wimberger sign) is almost pathognomonic.

**Differential Diagnosis**

**A. Congenital Syphilis**

1. **Newborns**—Sepsis, congestive heart failure, congenital rubella, toxoplasmosis, disseminated herpes simplex, cytomegalovirus infection, and hemolytic disease of the newborn have to be differentiated. A positive Coombs test and blood group incompatibility distinguish hemolytic disease.

2. **Young infants**—Injury to the brachial plexus, polio- myelitis, acute osteomyelitis, and septic arthritis must be differentiated from pseudoparalysis. Coryza due to viral infection often responds to symptomatic treatment. Rash (ammoniacal diaper rash) and scabies may be confused with a syphilitic eruption.

3. **Children**—Interstitial keratitis and bone lesions of tuberculosis are distinguished by positive tuberculin reaction and chest radiograph. Arthritis associated with syphilis is unaccompanied by systemic signs, and joints are nontender. Mental retardation, spasticity, and hyperactivity are shown to be of syphilitic origin by strongly positive serologic tests.

**B. Acquired Syphilis**

Herpes genitalis, traumatic lesions, and other venereal diseases must be differentiated from primary chancers.

**Treatment**

**A. Specific Measures**

Penicillin is the drug of choice for *T pallidum* infection. If the patient is allergic to penicillin, azithromycin, ceftriaxone or one of the tetracyclines may be used, but are of unknown efficacy.

**1. Congenital syphilis**

**A. Initial evaluation and treatment**—Newborns should not be discharged from the hospital until the mother’s serologic status for syphilis has been determined. Infants born to seropositive mothers require careful examination and quantitative nontreponemal (VDRL, RPR) syphilis testing. The same quantitative antitreponemal test used in evaluating the mother should be used in the infant so the titers can be compared. Maternal records regarding any prior diagnosis of syphilis, treatment, and follow-up titers should be reviewed. Infants should be further evaluated for congenital syphilis in any of the following circumstances:

- The maternal titer has increased fourfold.
- The infant’s titer is at least fourfold greater than the maternal titer.
- Signs of syphilis are found on examination.
- Maternal syphilis was not treated or was inadequately treated during pregnancy.
- Maternal syphilis was treated with a nonpenicillin regimen, or the regimen or dose of medication is undocumented.
- Maternal syphilis was treated during pregnancy, but therapy was completed less than 4 weeks prior to delivery.
- Maternal syphilis was treated appropriately during pregnancy, but without the appropriate decrease in maternal nontreponemal titers after treatment.

The complete evaluation of an infant for possible congenital syphilis includes complete blood count, liver function
tests, long bone radiographs, CSF examination (cell counts, glucose, and protein), CSF VDRL, and quantitative serologic tests. In addition, the placenta and umbilical cord should be examined pathologically using fluorescent antitreponemal antibody, if available. An ophthalmologic examination may also be done.

Treatment for congenital syphilis is indicated for infants with physical signs; umbilical cord or placenta positive for DFA-TP staining or darkfield examination; abnormal radiographs; elevated CSF protein or cell counts; reactive CSF VDRL; or serum quantitative nontreponemal titer that is more than fourfold higher than the maternal titer (using same test). Newborns with proved or suspected congenital syphilis should receive either (1) aqueous crystalline penicillin G, 50,000 U/kg per dose intravenously every 12 hours (if <1 week old) or (2) every 8 hours (if 1–4 weeks old) for 10 days. Procaine penicillin G, 50,000 U/kg in a single daily dose for 10 days is an alternative if compliance is assured. All infants diagnosed after age 4 weeks should receive 50,000 U/kg per dose aqueous crystalline penicillin intravenously every 4–6 hours for 10 days.

Additionally, treatment should be given to infants whose mothers have inadequately treated syphilis, to those whose mothers received treatment less than 1 month before delivery, to those whose mothers have undocumented or inadequate serologic response to therapy, and to those whose mothers were given nonpenicillin drugs to treat syphilis. In these instances, if the infant is asymptomatic, has a normal physical examination, normal CSF parameters, nonreactive CSF VDRL, normal bone films, quantitative nontreponemal titer less than fourfold of the mother's titer, and good follow-up is certain, some experts would give a single dose of penicillin G benzathine, 50,000 U/kg intramuscularly. If there is any abnormality in the preceding evaluation or if the CSF testing is not interpretable, the full 10 days of intravenous penicillin should be given. Close clinical and serologic monthly follow-up is necessary.

Asymptomatic, seropositive infants with normal physical examinations born to mothers who received adequate syphilis treatment (completed >4 weeks prior to delivery) and whose mothers have an appropriate serologic response (fourfold or greater decrease in titer) to treatment may be at lower risk for congenital syphilis. Some experts believe complete laboratory and radiographic evaluation in these infants (CSF and long bone films) is not necessary. Infants who meet the preceding criteria, who have nontreponemal titers less than fourfold higher than maternal titers, and for whom follow-ups are certain can be given benzathine penicillin G, 50,000 U/kg, administered intramuscularly in a single dose. Infants should be followed with quantitative serologic tests and physical examinations until the nontreponemal serologic test is negative (see discussion of follow-up, next). Rising titers or clinical signs usually occur within 4 months in infected infants, requiring a full evaluation (including CSF studies and long bone radiographs) and institution of intravenous penicillin therapy.

B. Follow-up for congenital syphilis—Children treated for congenital syphilis need physical examinations every 2–3 months after completion of therapy, and both physical examinations and quantitative VDRL or RPR tests should be performed until the tests become nonreactive. Repeat CSF examination, including a CSF VDRL test, every 6 months until normal is indicated for infants with a positive CSF VDRL reaction or with abnormal cell counts or protein in the CSF. A reactive CSF VDRL test at the 6-month interval is an indication for retreatment. Titers decline with treatment and are usually negative by 6 months. Repeat treatment is indicated for children with rising titers or stable titers that do not decline.

2. Acquired syphilis of less than 1 year’s duration—Benzathine penicillin G (50,000 U/kg, given intramuscularly, to a maximum of 2.4 million units) is given to adolescents with primary, secondary, or latent disease of less than 1 year’s duration. All children should have a CSF examination (with CSF VDRL) prior to commencing therapy, to exclude neurosyphilis. Adolescents and adults need a CSF examination if clinical signs or symptoms suggest neurologic involvement or if they are HIV-infected.

3. Syphilis of more than 1 year’s duration (late latent disease)—Syphilis of more than 1 year’s duration (without evidence of neurosyphilis) requires weekly intramuscular benzathine penicillin G therapy for 3 weeks. CSF examination and VDRL test should be done on all children and patients with coexisting HIV infection or neurologic symptoms. In addition, patients who have failed treatment or who were previously treated with an agent other than penicillin need a CSF examination and CSF VDRL.

4. Neurosyphilis—Aqueous crystalline penicillin G is recommended, 200,000–300,000 U/kg/d in four to six divided doses, given intravenously for 10–14 days. The maximum adult dose is 4 million units per dose. Some experts recommend following this regimen with an intramuscular course of benzathine G penicillin, 50,000 U/kg given once a week for 3 consecutive weeks, to a maximum dose of 2.4 million units.

B. General Measures

Penicillin treatment of early congenital or secondary syphilis may result in a dramatic systemic febrile illness termed the Jarisch–Herxheimer reaction. Treatment is symptomatic, with careful follow-up. Transfusion may be necessary in infants with severe hemolytic anemia.

**Prognosis**

Severe disease, if undiagnosed, may be fatal in the newborn. Complete cure can be expected if the young infant is given
penicillin. Serologic reversal usually occurs within 1 year. Treatment of primary syphilis with penicillin is curative. Permanent neurologic sequelae may occur in meningovascular syphilis.

Centers for Disease Control and Prevention (CDC) et al: Sexually transmitted diseases treatment guidelines, 2010. MMWR Recomm Rep 2010;59(RR-12) [PMID: 21160459].

RELAPSING FEVER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Episodes of fever, chills, malaise.
► Occasional rash, arthritis, cough, hepatosplenomegaly, conjunctivitis.
► Diagnosis suggested by direct microscopic identification of spirochetes in smears of peripheral blood. Diagnosis confirmed with serologic testing.

Prevention

Measures that decrease exposures to soft ticks and body lice will prevent most cases. Soft-bodied ticks often are found in rodent burrows or nests, so decreasing rodent access to homes and eliminating rodents in the home is helpful. Body-louse infestation can be treated with hygiene and pediculicides.

General Considerations

Relapsing fever is a vector-borne disease caused by spirochetes of the genus Borrelia. Epidemic relapsing fever is transmitted to humans by body lice (Pediculus humanus) and endemic relapsing fever by soft-bodied ticks (genus Ornithodoros). Tick-borne relapsing fever is endemic in the western United States. Although several hundred cases are reported per year, substantial underdiagnosis occurs. Transmission usually takes place during the warm months, when ticks are active and recreation or work brings people into contact with Ornithodoros ticks. B hermsii causes most tick-borne infection in the United States. Infection is often acquired in mountain camping areas and cabins. The ticks are nocturnal feeders and remain attached for only 5–20 minutes. Consequently, the patient seldom remembers a tick bite. Rarely, neonatal relapsing fever results from transplacental transmission of Borrelia. Both louse-borne and tick-borne relapsing fever may be acquired during foreign travel.

Clinical Findings

A. Symptoms and Signs

The incubation period is 2–18 days. The attack is sudden, with high fever, chills, sweats, tachycardia, nausea and vomiting, headache, myalgia, and arthralgia. After 3–10 days, the fever falls. The disease is characterized by relapses at intervals of 1–2 weeks and lasting 3–5 days. The relapses duplicate the initial attack but become progressively less severe. In louse-borne relapsing fever, there is usually a single relapse. In tick-borne infection, two to six relapses occur.

Hepatomegaly, splenomegaly, pneumonia, meningitis, and myocarditis may appear later in the course of the disease. An erythematous rash may be seen over the trunk and extremities, and petechiae may be present. Jaundice, iritis, conjunctivitis, cranial nerve palsies, and hemorrhage occur more commonly during relapses.

B. Laboratory Findings

During febrile episodes, the patient’s urine contains protein, casts, and occasionally erythrocytes; a marked polymorphonuclear leukocytosis is present; and about 25% of patients have a false-positive serologic test for syphilis. Spirochetes can be found in the peripheral blood by direct microscopy in approximately 70% of cases by darkfield examination or by Wright, Giemsa, or acridine orange staining of thick and thin smears. Spirochetes are not found during afebrile periods. Immunofluorescent antibody (or ELISA confirmed by Western blot) can help establish the diagnosis serologically. However, high titers of Borrelia hermsii can cross-react with Borrelia burgdorferi (the agent in Lyme disease) or Leptospira in immunofluorescent antibody assay, ELISA, and Western blots. Serologic specimens can be sent to the Division of Vector-Borne Infectious Diseases, Centers for Disease Control and Prevention, Fort Collins, CO 80522.

Differential Diagnosis

Relapsing fever may be confused with malaria, leptosprirosis, dengue, typhus, rat-bite fever, Colorado tick fever, Rocky Mountain spotted fever, collagen-vascular disease, or any fever of unknown origin.

Complications

Complications include facial paralysis, iridocyclitis, optic atrophy, hypochromic anemia, pneumonia, nephritis, myocarditis, endocarditis, and seizures. CNS involvement occurs in 10%–30% of patients.
INFECTIONS: BACTERIAL & SPIROCHETAL

Treatment

For children younger than age 8 years who have tick-borne relapsing fever, penicillin or erythromycin should be given for 10 days. Older children may be given doxycycline. Chloramphenicol is also efficacious and was often used in the past.

Severely ill patients should be hospitalized. Patients may experience a Jarisch-Herxheimer reaction (usually noted in the first few hours after commencing antibiotics). Isolation precautions are not necessary for relapsing fever. Contact precautions are recommended for patients with louse infestations.

Prognosis

The mortality rate in treated cases of relapsing fever is very low, except in debilitated or very young children. With treatment, the initial attack is shortened and relapses prevented. The response to antimicrobial therapy is dramatic.

Centers for Disease Control: Relapsing fever. Available at: http://www.cdc.gov/ncidod/dvbid/relapsingfever/

LEPTOSPIROSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Biphasic course lasting 2–3 weeks.
- Initial phase: high fever, headache, myalgia, and conjunctivitis.
- Apparent recovery for 2–3 days.
- Return of fever associated with meningitis.
- Jaundice, hemorrhages, and renal insufficiency (severe cases).
- Culture of organism from blood and CSF (early) and from urine (later), or direct microscopy of urine or CSF.
- Positive leptosporal agglutination test.

General Considerations

Leptospirosis is a zoonosis caused by many antigenically distinct but morphologically similar spirochetes. The organism enters through the skin or respiratory tract. Classically the severe form (Weil disease), with jaundice and a high mortality rate, was associated with infection with *Leptospira icterohaemorrhagiae* after immersion in water contaminated with rat urine. It is now known that a variety of animals (eg, dogs, rats, and cattle) may serve as reservoirs for pathogenic *Leptospira*, that a given serogroup may have multiple animal species as hosts, and that severe disease may be caused by many different serogroups.

In the United States, leptospirosis usually occurs after contact with dogs. Cattle, swine, or rodents may transmit the organism. Sewer workers, farmers, slaughterhouse workers, animal handlers, and soldiers are at risk for occupational exposure. Outbreaks have resulted from swimming in contaminated streams and harvesting field crops. In the United States, about 100 cases are reported yearly, about one-third of them in children.

Prevention

Preventive measures include avoidance of contaminated water and soil, rodent control, immunization of dogs and other domestic animals, and good sanitation. Gloves, boots, and other protective clothing can be worn when contact is unavoidable. Antimicrobial prophylaxis with doxycycline may be of value to certain high-risk occupational groups with short-term exposures. Doxycycline is not approved for use in children less than 8 years of age unless benefits exceed risk.

Clinical Findings

A. Symptoms and Signs

1. Initial phase—The incubation period is 4–19 days (mean, 10 days). Chills, fever, headache, myalgia (especially lumbar area and calves), conjunctivitis without exudate, photophobia, cervical lymphadenopathy, and pharyngitis commonly occur. The initial leptospiremic phase lasts for 3–7 days.

2. Phase of apparent recovery—Symptoms typically (but not always) subside for 2–3 days.

3. Systemic phase—Fever reappears and is associated with headache, muscular pain, and tenderness in the abdomen and back, and nausea and vomiting. Conjunctivitis and uveitis are common. Lung, heart, and joint involvement occasionally occur. These manifestations are due to extensive vasculitis.

   A. CNS involvement—The CNS is involved in 50%–90% of cases. Severe headache and mild nuchal rigidity are usual, but delirium, coma, and focal neurologic signs may be seen.

   B. Renal and hepatic involvement—In about 50% of cases, the kidney or liver is affected. Gross hematuria and oliguria or anuria is sometimes seen. Jaundice may be associated with an enlarged and tender liver.

   C. Gallbladder involvement—Leptospirosis may cause acalculous cholecystitis in children, demonstrable by abdominal ultrasound as a dilated, nonfunctioning gallbladder. Pancreatitis is unusual.
D. Hemorrhage—Petechiae, ecchymoses, and gastrointestinal bleeding may be severe.

E. Rash—A rash is seen in 10%–30% of cases. It may be maculopapular and generalized or may be petechial or purpuric. Occasionally erythema nodosum is seen. Peripheral desquamation of the rash may occur. Gangrenous areas are sometimes noted over the distal extremities. In such cases, skin biopsy demonstrates the presence of severe vasculitis involving both the arterial and the venous circulations.

B. Laboratory Findings

Leptospires are present in the blood and CSF only during the first 10 days of illness. They appear in the urine during the second week, where they may persist for 30 days or longer. Culture is difficult and requires specialized media and conditions. The WBC count often is elevated, especially when there is liver involvement. Serum bilirubin levels usually remain below 20 mg/dL. Other liver function tests may be abnormal, although the aspartate transaminase usually is elevated only slightly. An elevated serum creatine kinase is frequently found. CSF shows moderate pleocytosis (< 500/μL)—predominantly mononuclear cells—increased protein (50–100 mg/dL), and normal glucose. Urine often shows microscopic pyuria, hematuria, and, less often, moderate proteinuria (++, for greater). The ESR is elevated markedly. Chest radiograph may show pneumonitis.

Serologic antibodies measured by enzyme immunoassay may be demonstrated during or after the second week of illness. The confirmatory test of choice is a microscopic agglutination test, performed at the CDC. Leptospiral agglutinins generally reach peak levels by the third to fourth week. Fourfold or greater titer rise in acute and convalescent specimens is diagnostic. A PCR assay may be available at specialized research centers or through the CDC.

**Differential Diagnosis**

Fever and myalgia associated with the characteristic conjunctival injection should suggest leptospirosis. During the prodrome, malaria, typhoid, rheumatoid arthritis, brucellosis, and influenza may be suspected. Later, depending on the organ systems involved, a variety of other diseases need to be distinguished, including encephalitis, viral or tuberculous meningitis, viral hepatitis, glomerulonephritis, viral or bacterial pneumonia, rheumatic fever, subacute infective endocarditis, acute surgical abdomen, and Kawasaki disease (see Table 40–3).

**Treatment**

A. Specific Measures

Aqueous penicillin G (150,000 U/kg/d, given in four to six divided doses intravenously for 7–10 days) should be given when the diagnosis is suspected. Alternative agents include parenteral cefotaxime, ceftriaxone, or doxycycline. A Jarisch-Herxheimer reaction may occur. Oral doxycycline may be used for mildly ill patients. Doxycycline should not be used in children less than 8 years or pregnant women.

**B. General Measures**

Symptomatic and supportive care is indicated, particularly for renal and hepatic failure and hemorrhage. Contact isolation is recommended, due to potential transmission from contact with urine.

**Prognosis**

Leptospirosis is usually self-limiting and not characterized by jaundice. The disease usually lasts 1–3 weeks but may be more prolonged. Relapse may occur. There are usually no permanent sequelae associated with CNS infection, although headache may persist. The mortality rate in the United States is 5%, usually from renal failure. The mortality rate may reach 20% or more in elderly patients who have severe kidney and hepatic involvement.

Centers for Disease Control and Prevention: Leptospirosis. Available at: http://www.cdc.gov/leptospirosis/

**LYME DISEASE**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Characteristic skin lesion (erythema migrans) 3–30 days after tick bite.
- Arthritis, usually pauciarticular, occurring about 4 weeks after appearance of skin lesion. Headache, chills, and fever.
- Residence or travel in an endemic area during the late spring to early fall.

**General Considerations**

Lyme disease is a subacute or chronic spirochetal infection caused by *B. burgdorferi* and transmitted by the bite of an
infected deer tick (*Ixodes* species). The disease was known in Europe for many years as tick-borne encephalomyelitis, often associated with a characteristic rash (erythema migrans). Discovery of the agent and vector followed investigation of an outbreak of pauciarticular arthritis in Lyme, Connecticut, in 1977.

Although cases are reported from many countries, the most prominent endemic areas in the United States include the Northeast, upper Midwest, and West Coast. The northern European countries also have high rates of infection. Nearly 30,000 confirmed or probable cases were reported in the United States in 2010. Knowledge of the local epidemiology is important as Lyme disease is common in some areas of northeastern United States, but rare in the mountain states. The disease is spreading as a result of increased infection in and distribution of the tick vector. Most cases with rash are recognized in spring and summer, when most tick bites occur; however, because the incubation period for joint and neurologic disease may be months, cases may present at any time. *Ixodes* ticks are very small, and their bite is often unrecognized.

**Clinical Findings**

**A. Symptoms and Signs**

Erythema chronicum migrans, the most characteristic feature of Lyme disease, is recognized in 60%–80% of patients. Between 3 and 30 days after the bite, a ring of erythema develops at the site and spreads over days. It may attain a diameter of 20 cm. The center of the lesion may clear (resembling tinea corporis), remain red, or become raised (suggesting a chemical or infectious cellulitis). Mild tenderness may occur. Many patients are otherwise asymptomatic. Some have fever (usually low-grade), headache, and myalgias. Multiple satellite skin lesions, urticaria, or diffuse erythema may occur. Untreated, the rash lasts days to 3 weeks.

In up to 50% of patients, arthritis develops several weeks to months after the bite. Recurrent attacks of migratory, monoarticular, or pauciarticular arthritis involving the knees and other large joints occur. Each attack lasts for days to a few weeks. Fever is common and may be high. Complete resolution between attacks is typical. Chronic arthritis develops in less than 10% of patients, more often in those with the DR4 haplotype.

Neurologic manifestations develop in up to 20% of patients and usually consist of Bell palsy, aseptic meningitis (which may be indistinguishable from viral meningitis), or polyradiculitis. Peripheral neuritis, Guillain-Barré syndrome, encephalitis, ataxia, chorea, and other cranial neuropathies are less common. Seizures suggest another diagnosis. Untreated, the neurologic symptoms are usually self-limited but may be chronic or permanent. Although fatigue and nonspecific neurologic symptoms may be prolonged in a few patients, Lyme disease is not a cause of chronic fatigue syndrome. Self-limited heart block or myocardial dysfunction occurs in about 5% of patients.

**B. Laboratory Findings**

Most patients with only rash have normal laboratory tests. Children with arthritis may have moderately elevated ESRs and WBC counts; the antinuclear antibodies and rheumatoid factor tests are negative or nonspecific; streptococcal antibodies are not elevated. Circulating IgM cryoglobulins may be present. Joint fluid may show up to 100,000 cells with a polymorphonuclear predominance, normal glucose, and elevated protein and immune complexes; Gram stain and culture are negative. In patients with CNS involvement, the CSF may show lymphocytic pleocytosis and elevated protein; the glucose and all cultures and stains are normal or negative. Abnormal nerve conduction may be present with peripheral neuropathy.

**C. Diagnosis**

Lyme disease is a clinical diagnosis. Local epidemiology, history of travel to endemic areas, physical examination, and laboratory features are important to consider. The causative organism is difficult to culture. Serologic testing may support the clinical diagnosis. Antibody testing should be performed in experienced laboratories. Serologic diagnosis of Lyme disease is based on a two-test approach: an ELISA and an immunoblot to confirm a positive or indeterminate ELISA. Antibodies may not be detectable until several weeks after infection has occurred; therefore, serologic testing in children with a typical rash is not recommended. Therapy early in disease may blunt antibody titers. Recent studies have shown considerable intralaboratory and interlaboratory variability in titers reported. Serologic testing of patients with nonspecific complaints from low prevalence areas results in falsely positive tests. Overdiagnosis of Lyme disease based on atypical symptoms and positive serology appears to be common. Sera from patients with syphilis, HIV, and leptospirosis may give false-positive results. Patients who receive appropriate treatment for Lyme disease may remain seropositive for years. Diagnosis of CNS disease requires objective abnormalities of the neurologic examination, laboratory or radiographic studies, and consistent positive serology.

**Differential Diagnosis**

Aside from the disorders already mentioned, the rash may resemble pityriasis, erythema multiforme, a drug eruption, or erythema nodosum. Erythema chronicum migrans is nonscaly, minimally tender or nontender, and persists longer in the same place than many of the more common childhood erythematous rashes. The arthritis may resemble juvenile rheumatoid arthritis, reactive arthritis, septic
arthriti, reactive effusion from a contiguous osteomyelitis, rheumatic fever, leukemic arthritis, systemic lupus erythematosus, and Henoch-Schönlein purpura. Spontaneous resolution in a few days to weeks helps differentiate Lyme disease from juvenile rheumatoid arthritis, in which arthritis lasting a minimum of 6 weeks is required for diagnosis. The neurologic signs may suggest idiopathic Bell palsy, viral or parainfectious meningitis or meningoencephalitis, lead poisoning, psychosomatic illness, and many other conditions.

**Prevention**

Prevention consists of avoidance of endemic areas, wearing long sleeves and pants, frequent checks for ticks, and application of tick repellents. Ticks usually are attached for 24–48 hours before transmission of Lyme disease occurs. Ticks should be removed with a tweezer by pulling gently without twisting or excessive squeezing of the tick. Permethrin sprayed on clothing decreases tick attachment. Repellents containing high concentrations of N,N-Diethyl-meta-toluamide (DEET) may be neurotoxic and should be used cautiously in young children and infants and washed off when tick exposure ends. Prophylactic antibiotics for tick bites in asymptomatic individuals is not usually recommended.

**Treatment**

Antimicrobial therapy is beneficial in most cases of Lyme disease. It is most effective if started early. Prolonged treatment is important for all forms. Relapses occur in some patients on all regimens.

**A. Rash, Early Infections**

Amoxicillin, 50 mg/kg/d orally in two divided doses (to a maximum of 2 g/d) for 14–21 days can be used for children of all ages. Doxycycline (100 mg orally twice a day) for 14–21 days may be used for children older than age 8 years. Erythromycin (30 mg/kg/d) or cefuroxime is used in penicillin-allergic children, although erythromycin may be less effective than amoxicillin.

**B. Arthritis**

The amoxicillin or doxycycline regimen (same dosage as for the rash) should be used, but treatment should continue for 4 weeks. Parenteral ceftriaxone (50–75 mg/kg/d) or penicillin G (300,000 U/kg/d, given intravenously in four divided doses for 2–4 weeks) is used for persistent arthritis.

**C. Bell Palsy**

The same oral drug regimens may be used for 3–4 weeks.

**D. Other Neurologic Disease or Cardiac Disease**

Parenteral therapy for 2–4 weeks is recommended with either ceftriaxone (50–75 kg/d in one daily dose) or penicillin G (300,000 U/kg/d intravenously in four divided doses).

Infections: Parasitic & Mycotic

Kevin Messacar, MD
Samuel R. Dominguez, MD, PhD
Myron J. Levin, MD

**PARASITIC INFECTIONS**

Parasitic diseases are common and may present clinically in a variety of ways (Table 43–1). Although travel to endemic areas suggests particular infections, many parasites are transmitted through fomites or acquired from contact with human carriers and can occur anywhere. Some of the less common parasitic infections and those seen primarily in the developing world are presented in abbreviated form in Table 43–2.

**Selection of Patients for Evaluation**

The incidence of parasitic infections varies greatly with geographic area. Children who have traveled or lived in areas where parasitic infections are endemic are at risk for infection with a variety of intestinal and tissue parasites. Children who have resided only in developed countries are usually free of tissue parasites (except *Toxoplasma*). Searching for intestinal parasites is expensive for the patient and time-consuming for the laboratory. More than 90% of ova and parasite examinations performed in most hospital laboratories in the United States are negative; many have been ordered inappropriately on patients without exposure to endemic areas. An approach to determining which children with diarrhea need such examinations is presented in Figure 43–1. It can be more cost-effective to empirically treat symptomatic US immigrants with albendazole for common intestinal parasites and to investigate only those whose symptoms persist.

Immunodeficient children are very susceptible to protozoal intestinal infections. Multiple opportunists are frequently identified, and the threshold for ordering tests should be low for these children.

**Specimen Processing**

For tissue parasites, contact the laboratory for proper collection procedures. For intestinal parasites, diarrheal stools may contain trophozoites that die rapidly during transport. The specimen should be either examined immediately or placed in a stool fixative such as polyvinyl alcohol. Fixative vials for home collection of stool are commercially available. They may contain toxic compounds, so they should be stored safely. Fixed specimens are stable at room temperature. Formed stools usually contain cysts that are more stable. It is also best to fix these after collection, although they may be reliably examined after transport at room temperature. The US Centers for Disease Control and Prevention (CDC) have created a website (http://dpd.cdc.gov/dpdx) to assist in the laboratory diagnosis of common parasitic diseases, including specimen collection and processing.

**Eosinophilia & Parasitic Infections**

Although certain parasites commonly cause eosinophilia, in developed countries other causes are much more common. These include allergies, drugs, and other infections. Heavy intestinal nematode infection causing eosinophilia is easily detected on a single ova and parasite examination. Light nematode infections and common protozoal infections—giardiasis, cryptosporidiosis, and amebiasis—rarely cause eosinophilia. Eosinophilia is also unusual or minimal in more serious infections such as amebic liver abscess and malaria.

The most common parasitic infection in the United States that causes significant eosinophilia with negative stool examination is toxocarasis. In a young child with unexplained eosinophilia and a negative stool examination for parasites, a serologic test for *Toxocara* may be the next appropriate test. Trichinosis, which is a rare parasitic infection in the United States, causes marked eosinophilia. Strongyloidiasis is a cause of eosinophilia that may be difficult to diagnose with stool examinations.

The differential diagnosis of eosinophilia is broad for patients who have been in developing countries (see Table 43–1).

▲ Figure 43–1. Parasitologic evaluation of acute diarrhea.

- Can progress to coma, seizures.
- Malaria parasites in peripheral blood smear.

General Considerations

Malaria causes approximately 1 million deaths each year, over 80% of which occur in children younger than 5 years of age in sub-Saharan Africa. Over the past 5 years, global efforts towards malaria prevention and treatment have led to declining mortality and morbidity. Approximately 1500 imported cases are diagnosed in the United States each year; local transmission may occasionally take place from imported cases. Human malaria is caused by five Plasmodium species—Plasmodium vivax (most common), Plasmodium falciparum (most virulent), Plasmodium ovale (similar to P vivax), Plasmodium malariae, and Plasmodium knowlesi (a primate parasite recently recognized as a cause of malaria in humans).

The female Anopheles mosquito transmits the parasites. An infected mosquito inoculates sporozoites into the
bloodstream of a susceptible host, resulting in infection of hepatocytes. In the hepatic phase, the parasites mature into schizonts, which rupture and release merozoites into the circulation. The parasites infect and rupture red blood cells in the erythroclytic phase, as they mature from trophozoites to schizonts and release additional merozoites. In early stages of infection, asynchronous erythrocytic cycles of hemolysis commonly cause daily fevers. Eventually, synchronous erythrocytic cycles begin as parasites rupture the infected cells at more regular 48- or 72-hour intervals. Survival is associated with a progressive decrease in intensity of cycles. Relapses years later may occur from persistent hepatic infection, which occurs in \textit{P. vivax} and \textit{P. ovale} infections.

Susceptibility varies genetically; certain red cell phenotypes are partially resistant to \textit{P. falciparum} infection (hemoglobin S, hemoglobin F, thalassemia, and possibly glucose-6-phosphate dehydrogenase [G6PD] deficiency). The worldwide distribution of malaria species is determined to some extent by host genetic factors that have evolved in response to selective pressure from malaria. The absence of \textit{P. vivax} from Africa reflects the lack of specific Duffy blood group substances among most native Africans. Recurrent infections result in acquired species-specific immunity, which does not prevent infection, but decreases parasitemia and symptoms. Normal splenic function is an important factor because of the immunologic and filtration functions of the spleen. Asplenic persons develop rapidly progressive malaria with many circulating infected erythrocytes (including mature forms of \textit{P. falciparum}). Maternal immunity protects the neonate.

\section*{Clinical Findings}

\subsection*{A. Symptoms and Signs}

Clinical manifestations vary according to species, strain, and host immunity. Fever and vomiting are the most common presenting symptoms in children. Infants commonly present with recurrent bouts of fever, irritability, poor feeding, vomiting, jaundice, and splenomegaly. Rash is usually absent, which helps distinguish malaria from some viral infections in patients presenting with similar symptoms. In older children, the classic symptoms of fever with chills, rigors, headache, backache, myalgia, and fatigue are more easily elicited. Fever may be cyclic (every 48 hours for all but \textit{P. malariae} infection, in which it occurs every 72 hours) or irregular (most commonly observed with \textit{P. falciparum}). Between attacks, patients may look quite well. If the disease is untreated, relapses cease within a year in \textit{P. falciparum} and within several years in \textit{P. vivax} infections, but may recur decades later with \textit{P. malariae} infection. Infection during pregnancy often causes intraterine growth restriction or premature delivery but rarely true fetal infection.

Physical examination in patients with uncomplicated cases may show only mild splenomegaly and anemia.

\subsection*{B. Laboratory Findings}

The diagnosis of malaria relies on detection of one or more of the five human plasmodia in thick and thin blood smears. Three separate sets of thick and thin smears separated by 12–24 hours in a 72-hour period are recommended to rule out malaria infection. Thick smears are most sensitive for detection of small numbers of malaria parasites; thin smears allow identification of species and semiquantitative determination of percentage of parasitemia.

Most acute infections are caused by \textit{P. vivax}, \textit{P. ovale}, or \textit{P. falciparum}, although 5%–7% are due to multiple species. Identification of the \textit{Plasmodium} species relies on morphologic criteria and requires an experienced observer (Table 43–3). Bench aids to assist in the identification of \textit{Plasmodium} species can be found at http://www.dpd.cdc.gov/dpdx/HTML/Malaria.htm. A new US Food and Drug Administration (FDA)-approved antigen detection test is available and approved for rapid diagnostic testing of malaria. This test should be used in conjunction with microscopic examination to confirm diagnosis, look for mixed infection, and quantitate degree of parasitemia. The rapid antigen test has poor sensitivity for low levels of parasitemia. Up-to-date information on rapid diagnostic testing for malaria can be found at www.cdc.gov/malaria/diagnosis_treatment/index.html. Alternative techniques of similar or higher diagnostic accuracy for \textit{P. falciparum} include DNA hybridization and polymerase chain reaction (PCR), which are only available in research and reference laboratories as well as at CDC and some health departments.

The degree of parasitemia determined from thin smears is particularly useful in the management of infections caused by \textit{P. falciparum} and \textit{P. knowlesi}, in which high parasitemia (> 5% infected erythrocytes) is associated with high morbidity and mortality and requires hospitalization. Treatment response of \textit{P. falciparum} and chloroquine-resistant \textit{P. vivax} infections is best monitored by daily parasitemia assays.

\begin{table}[h]
\centering
\begin{tabular}{|l|c|c|}
\hline
 & \textit{Plasmodium falciparum} & \textit{P. vivax, P. ovale} \\
\hline
Multiply-infected erythrocytes & Common & Rare \\
Mature trophozoites or schizonts & Absent* & Common \\
Schüffner dots & Absent & Common \\
Enlarged erythrocytes & Absent & Common \\
Banana-shaped gametocytes & Common & Absent \\
\hline
\end{tabular}
\caption{Differentiation of malaria parasites on blood smears.}
\end{table}

*Usually sequestered in the microcirculation. Rare cases with circulating forms have extremely high parasitemia and a poor prognosis.
Constant or increased number of infected erythrocytes after 48 hours of treatment or after the second hemolytic crisis suggests an inadequate therapeutic response.

Hemolytic anemia and thrombocytopenia are common; the incidence of leukocytosis is variable.

**Differential Diagnosis**

Relapsing fever may be associated with borreliosis, brucellosis, sequential common infections, Hodgkin disease, juvenile rheumatoid arthritis, or rat-bite fever. Other common causes of high fever and headache include influenza, *Mycoplasma pneumoniae* or enteroviral infection, sinusitis, meningitis, enteric fever, tuberculosis, occult pneumonia, or bacteremia. In patients returning from tropical areas with fever, headache, and jaundice, leptospirosis and yellow fever should be included in the differential diagnosis. Clinical features may not reliably distinguish severe malaria from other severe infections in children, so a high index of suspicion in patients with exposure in endemic areas is necessary. Malaria may also coexist with other diseases.

**Complications & Sequelae**

Severe complications, which are limited to *P. falciparum* and *P. knowlesi* infection, result from hemolysis, microvascular obstruction, and tissue ischemia. The most common complications of malaria in children are cerebral malaria, respiratory distress, severe anemia, and/or hypoglycemia. Cerebral malaria is the most serious and life-threatening complication of malaria in children and may progress to seizures, coma, and death. Approximately 20% of children with cerebral malaria die and 10% have long-term neurologic sequelae. Signs of severe malaria in children include altered mental status, seizures, respiratory distress, hypoglycemia, acidosis, and parasitemia greater than 5%.

**Prevention**

Malaria chemoprophylaxis should be instituted 2 weeks (weekly regimens) to 2 days (daily regimens) before traveling to an area of endemic infection to permit alternatives if the drug is not tolerated. Because the antimalarial drugs recommended for prophylaxis do not kill sporozoites, therapy should be continued for 1 week (atovaquone-proguanil) or 4 weeks (all other regimens) after returning from an endemic area to cover infection acquired at departure.

No drug regimen guarantees protection against malaria. If fever develops within 1 year (particularly within 2 months) after travel to an endemic area, the possibility of malaria should be considered. Insect repellents, insecticide-impregnated bed nets, and proper clothing are important adjuncts for malaria prophylaxis.

For a full discussion regarding currently recommended medications for malaria prophylaxis, please see the corresponding section in Chapter 45.

**Treatment**

Treatment for malaria includes a variety of supportive strategies in addition to the antimalarial drugs. It is advisable to hospitalize nonimmune patients infected with *P. falciparum* and *P. knowlesi* until a decrease in parasitemia is demonstrated, indicating that treatment is effective and severe complications are unlikely to occur. Patients with signs of severe malaria (parasitemia > 5%, cerebral malaria, acidosis, hypoglycemia, shock) require intensive care and parenteral treatment. Malaria due to *P. knowlesi* should be treated like *P. falciparum* malaria as it might progress rapidly into severe disease.

Partially immune patients with uncomplicated *P. falciparum* and *P. knowlesi* infection and nonimmune persons infected with *P. vivax*, *P. ovale*, or *P. malariae* can receive treatment as outpatients if follow-up is reliable. For children, hydration and treatment of hypoglycemia are of utmost importance. Anemia, seizures, pulmonary edema, and renal failure require conventional management. Corticosteroids are contraindicated for cerebral malaria because of increased mortality. In severe malaria, exchange transfusion can be lifesaving, particularly in nonimmune persons with parasitemia greater than 10%.

Choice of antimalarial treatment depends on the immune status of the person, *plasmodium* species, degree of parasitemia, and resistance patterns in the geographical region of acquisition. An algorithm for the treatment of malaria is shown in Figure 43–2 and a description of the recommended antimalarial drugs available in the United States is provided in Table 43–4. Updated treatment guidelines are available at the Centers for Disease Control and Prevention (http://www.cdc.gov/malaria/diagnosis_treatment/treatment.html). Artemisinin derivatives clear parasites very rapidly and are widely used as key components, often as first-line therapy, in malaria treatment worldwide. These are available in the United States for the treatment of severe malaria only by contacting the CDC (http://www.cdc.gov/malaria/diagnosis_treatment/artesunate.html) or the Malaria Hotline at 770-488-7788.

Taylor SM et al: Does this patient have malaria? JAMA 2010;304:2048–2056 [PMID: 21057136].
History of travel to malaria-endemic area or clinical suspicion of malaria

Perform thick and thin blood films and read in < 12 h

Blood film positive?

Repeat blood films every 12–24 h for 48–72 h

No

Yes

Blood film positive?

Calculate parasite density

Consider alternative diagnosis

Evaluate clinical status and disease severity

Uncomplicated malaria

Determine infecting species using blood film

Plasmodium falciparum or species not yet identified

Non-falciparum species

Acquired in chloroquine-resistant area

Acquired in chloroquine-sensitive area

Plasmodium malariae

Plasmodium ovale or Plasmodium vivax acquired outside Papua, New Guinea, or Indonesia

P. vivax acquired in Papua, New Guinea, or Indonesia

Oral quinine plus tetracycline, doxycycline, or clindamycin or atovaquone-proguanil or mefloquine if above not available

Intravenous quinidine plus tetracycline, doxycycline, or clindamycin

Admit to intensive care unit

Monitor cardiac function continuously and monitor blood pressure frequently

Monitor parasitemia, glucose, hemoglobin, and electrolytes periodically

Prevent and treat complications

Consider exchange transfusion if parasite density >10% or if patient has altered mental status, nonvolume overload pulmonary edema, or renal complications

Switch to oral antimalarial medication when possible

Repeat blood films if symptoms recur

Primary if not G6PD deficient if G6PD deficient, counsel about possibility of recurrence

Admit to hospital

Monitor symptoms daily

Repeat blood films daily until negative or if discharged prior to a negative film, at day 7

Repeat blood films every 12–24 h for 48–72 h

Yes

No

Yes

No

Tetracycline (oral or IV) | *P. falciparum* from chloroquine-resistant areas | Oral: 250 mg orally 4 times daily × 7 d | 25 mg/kg/d orally divided 4 times daily × 7 d | See doxycycline | See doxycycline

| *P. vivax* from chloroquine-resistant areas (in combination with quinine-quinidine) | IV: dosage same as for oral | IV: dosage same as for oral |  |

G6PD, glucose-6-phosphate dehydrogenase; IV, intravenous.

*Pediatric dosage should never exceed adult dosage.

*Extrapolated from chloroquine literature.

*Mefloquine should not be used to treat* *P. falciparum* infections acquired in the following areas: borders of Thailand with Burma (Myanmar) and Cambodia, western provinces of Cambodia, eastern states of Burma (Myanmar), border between Burma and China, Laos along borders of Laos and Burma (and adjacent parts of Thailand-Cambodia border), and southern Vietnam due to resistant strains.

*Quinine sulfate capsule manufactured in the United States is in a 324-mg dose; therefore, two capsules should be sufficient for adult dosing.

*Nausea, vomiting, headache, tinnitus, deafness, dizziness, and visual disturbances.

*Refer to quinidine gluconate, package insert (Eli Lilly Co, Indianapolis, Ind, February 2002).

2. Babesiosis

*Babesia microti* is a malaria-like protozoan that infects humans bitten by infected *Ixodes scapularis* (deer tick), one of its intermediate hosts and vectors. After inoculation, the protozoan penetrates erythrocytes and starts an asynchronous cycle that causes hemolysis. In the United States, the majority of cases occur in the Northeast and upper Midwest from May to October. Babesia infection is also a transfusion-transmissible disease.

**Clinical Findings**

**A. Symptoms and Signs**

The incubation period is 1–4 weeks after tick bite, or 1–9 weeks after blood transfusion. Many times the tick bite is unnoticed. Approximately half of infected children are asymptomatic. Symptoms are nonspecific and most commonly include sustained or cyclic fever up to 40.9°C, shaking chills, and sweats. Other associated nonspecific symptoms include malaise, fatigue, anorexia, arthralgias, myalgias, and headache. Physical examination findings are usually minimal, but may include hepatosplenomegaly, jaundice, or dark urine. The disease is usually self-limited, causing symptoms for 1–2 weeks that may persist for months. Severe cases have been described in asplenic patients and immunocompromised hosts. Because *Babesia*, *Borrelia burgdorferi*, and *Anaplasma phagocytophilum* share a common vector, physicians should consider the possibility of coinfection in patients diagnosed with any of these pathogens.

**B. Laboratory Findings**

The diagnosis is made by identifying babesial parasites in blood by microscopic evaluation of thin or thick blood smears or by PCR amplification of babesial DNA. Babesia parasites are intraerythrocytic organisms that resemble *P. falciparum* ring forms. The tetrad form (Maltese cross), if visualized, is pathognomonic. Specific serologic tests are also available through the CDC. Hemolytic anemia, as well as thrombocytopenia, is common.

**Treatment**

Azithromycin (10 mg/kg up to 500 mg on the first day, followed by 5 mg/kg up to 250 mg/day) in combination with atovaquone (20 mg/kg, up to 750 mg, twice a day) for 7–10 days is the treatment of choice for mild to moderate disease. It has been found to be efficacious and causes fewer adverse side effects than other regimens. For severely ill patients, clindamycin (10 mg/kg, up to 600 mg, every 8 hours) in combination with quinine (8 mg/kg, up to 650 mg, every 8 hours) is standard of care. Longer courses of treatment may be needed in immunocompromised patients. Partial or complete RBC exchange transfusion is indicated for persons with severe babesiosis, as indicated by high-grade parasitemia (≥ 10%); significant hemolysis; or renal, hepatic, or pulmonary compromise.

---

3. Toxoplasmosis

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Congenital toxoplasmosis: chorioretinitis, microphthalmia, strabismus, microcephaly, hydrocephaly, convulsions, psychomotor retardation, intracranial calcifications, jaundice, hepatosplenomegaly, abnormal blood cell counts.
- Acquired toxoplasmosis in an immunocompetent host: lymphadenopathy, hepatosplenomegaly, rash.
- Acquired or reactivated toxoplasmosis in an immunocompromised host: encephalitis, chorioretinitis, myocarditis, and pneumonitis.
- Ocular toxoplasmosis: chorioretinitis.
- Serologic evidence of infection with *Toxoplasma gondii* or demonstration of the agent in tissue or body fluids.

**General Considerations**

*Toxoplasma gondii* is a worldwide parasite of animals and birds. Felines, the definitive hosts, excrete oocysts in their feces. Ingested mature oocysts or tissue cysts lead to tachyzoite invasion of intestinal cells. Intracellular replication of the tachyzoites causes cell lysis and spread of the infection to adjacent cells or to other tissues via the bloodstream. In chronic infection, *T. gondii* appears in bradyzoite-containing tissue cysts that do not trigger an inflammatory reaction. In immunocompromised hosts, tachyzoites are released from cysts and begin a new cycle of infection.

The two major routes of *Toxoplasma* transmission to humans are oral and congenital. Oral infection occurs after ingestion of cysts from food, water, or soil contaminated with cat feces or from ingestion of undercooked meat or other food products that contain cysts. Oocysts survive for up to 18 months in moist soil. Oocyst survival is limited in
dry, very cold, or very hot conditions, and at high altitude, which probably accounts for the lower incidence of toxoplasmosis in these climatic regions. In the United States, less than 1% of cattle and 25% of sheep and pigs are infected with toxoplasmosis. In humans, depending on geographic area, seropositivity increases with age from 0 to 10% in children younger than age 10 years to 3%–70% in adults.

Congenital transmission occurs during acute infection of pregnant women. Rarely, fetal infection has been documented in immunocompromised mothers who have chronic toxoplasmosis. Treatment during pregnancy decreases transmission by 60%.

**Clinical Findings**

Clinical toxoplasmosis can be divided into four groups: (1) congenital infection, (2) acquired in the immunocompetent host, (3) acquired or reactivated in the immunocompromised host, and (4) ocular disease.

**A. Congenital Toxoplasmosis**

Congenital toxoplasmosis is the result of acute infection during pregnancy and occurs in 1 in 3000 to 1 in 10,000 live births in the United States. The rate of transmission and disease severity in the baby vary according to when in pregnancy the infection is acquired. First-trimester infections lead to congenital infections about 10%–20% of the time, but the clinical disease is severe with microcephaly or hydrocephaly, severe chorioretinitis, hearing loss, convulsions, abnormal cerebrospinal fluid (CSF) (xanthochromia and mononuclear pleocytosis), cerebral calcifications, and mental retardation. Other findings include strabismus, eye palsy, maculopapular rash, pneumonitis, myocarditis, hepatosplenomegaly, jaundice, thrombocytopenia, lymphocytosis and monocytosis, and an erythroblastosis-like syndrome. Infection of a mother in the third trimester results in 70%–90% rate of congenital infection, but the majority of these children are asymptomatic at birth. Many of these children, however, will go on to develop ocular disease later and some will have subtle neurologic deficits.

**B. Acquired Toxoplasma Infection in the Immunocompetent Host**

Typically, acquired infection in the immunocompetent host is asymptomatic. About 10%–20% of patients develop lymphadenopathy and/or a flu-like illness. The nodes are discrete, variably tender, and do not suppurate. Cervical lymph nodes are most frequently involved, but any nodes may be enlarged. Less common findings include fever, malaise, myalgias, fatigue, hepatosplenomegaly, low lymphocyte counts (usually < 10%), and liver enzyme elevations. Unilateral chorioretinitis may occur. The disease is self-limited, although lymph node enlargement may persist or may wax and wane for a few months to 1 or more years.

Toxoplasmic lymphadenitis must be distinguished from other causes of infectious mononucleosis-like syndromes (< 1% are caused by *Toxoplasma*). Recovery typically occurs without any specific antiparasitic treatment.

**C. Acute Toxoplasmosis in the Immunodeficient Host**

Patients infected with human immunodeficiency virus (HIV), and those with lymphoma, leukemia, or transplantation, are at high risk for developing severe disease (most commonly central nervous system [CNS] disease, but also chorioretinitis, myocarditis, or pneumonitis) following acute infection or reactivation. Toxoplasmic encephalitis is one of the most common causes of mass lesions in the brains of persons with HIV/AIDS.

**D. Ocular Toxoplasmosis**

Ocular toxoplasmosis is an important cause of chorioretinitis in the United States. It can result from reactivation of congenital infection or acquired infection. Congenitally infected individuals are usually asymptomatic until the second or third decade of life when symptomatic eye disease occurs due to the rupture of tissue cysts and the release of bradyzoites and tachyzoites into the retina. Typically, ocular toxoplasmosis presents as a focal necrotizing retinochoroiditis often associated with a preexistent chorioretinal scar, and variable involvement of the vitreous, retinal blood vessels, optic nerve, and anterior segment of the eye. The appearance of the ocular lesion is not specific and mimics other granulomatous ocular diseases.

**E. Diagnostic Findings**

Serologic tests are the primary means of diagnosis, but results must be interpreted carefully. Reference laboratories with special expertise in toxoplasma serologic assays and their interpretation are essential for establishing a diagnosis and are preferred. Active infection can also be diagnosed by PCR of blood or body fluids; by visualization of tachyzoites in histologic sections or cytology preparations, cysts in placenta or fetal tissues; or by characteristic lymph node histology. IgG antibodies become detectable 1–2 weeks after infection, peak at 1–2 months, and thereafter persist for life. IgM antibodies, measured by ELISA (enzyme-linked immunosorbert assay) or particle agglutination, appear earlier and decline faster than IgG antibodies, but can last for 12–18 months after acute infection. Absence of both serum IgG and IgM virtually rules out the diagnosis of toxoplasmosis. Acute toxoplasmosis in an immunocompetent host is best documented by analyzing IgG and IgM in paired blood samples drawn...
3 weeks apart. Because high antibody titers (IgM or IgG) can persist for several months after acute infection, a single high-titer determination is nondiagnostic; seroconversion or a fourfold increase in titer confirms the diagnosis. In the immunocompromised host, serologic tests are not sensitive, and active infection is documented by PCR or finding tachyzoites by histologic examination.

The diagnosis of toxoplasmosis in the older child with visual complaints is usually made by finding *T. gondii* IgG or IgM antibodies in the serum combined with the presence of a typical eye lesion. The diagnosis can be confirmed by detecting *T. gondii* DNA by PCR in the aqueous humor.

Diagnosis of congenital infection, which can be difficult, is made by a combination of serologic testing, parasite isolation, and clinical findings. Prenatally, diagnosis can be made by PCR of amniotic fluid. Postnatally, evaluation of the baby should include *Toxoplasma*-specific IgG, IgM, IgA, and IgE of the newborn and mother. IgM antibodies indicate an immune response by the infant. Persistence of the other antibodies also indicates infection of the infant. Blood, CSF, and amniotic fluid specimens should be assayed by PCR for the presence of *T. gondii* in a reference laboratory. In addition, the child should have thorough ophthalmologic, auditory, and neurologic evaluation; a lumbar puncture; and computed tomographic (CT) scan of the head (to detect CNS calcifications). A congenital infection is confirmed serologically by detecting persistent or increasing IgG antibody levels compared to the mother, persistently positive IgG antibodies beyond the first year of life, and/or a positive *T. gondii*-specific IgM or IgA antibody test.

**Differential Diagnosis**

Congenital toxoplasmosis must be differentiated from infection with cytomegalovirus, rubella, herpes simplex, syphilis, listeriosis, erythroblastosis, and the encephalopathies that accompany degenerative diseases. Acquired infection can mimic viral, bacterial, or lymphoproliferative disorders. Ocular toxoplasmosis can mimic other infectious, noninfectious, and neoplastic ocular conditions.

**Prevention**

Primary prevention of toxoplasmosis in pregnant women (and immunocompromised patients) is an essential public health goal and guidelines have been published by the CDC. These include (1) cook meat until well-done 150°F–170°F (no longer pink in center); (2) peel and/or wash fruits and vegetables thoroughly before eating; (3) wash hands, cutting boards, kitchen surfaces, and utensils after contact with raw meat; (4) avoid drinking untreated water from unsanitary sources; (5) wear gloves when gardening or coming in contact with soil or sand, as cat feces may contaminate them; and (6) if possible, pregnant women should avoid changing cat litter. If they cannot avoid changing cat litter, they should change it daily as oocysts require 48–72 hours to sporulate and become infectious. Serologic screening of pregnant women remains a controversial tool in the prevention of congenital toxoplasmosis.

**Treatment**

Treatment of acute toxoplasmosis in the immunocompetent host does not require specific therapy, unless the infection occurs during pregnancy. Toxoplasmic chorioretinitis presenting beyond infancy is treated the same way regardless of whether it is due to reactivation or primary infection. Treatment consists of oral pyrimethamine (2 mg/kg maximum 200 mg loading dose followed by 1 mg/kg daily, maximum 75 mg) plus sulfadiazine (100 mg/kg daily, maximum 1500 mg), given with leucovorin (10–20 mg three times a week). In addition, corticosteroids (prednisone 1 mg/kg daily) are given when lesions threaten vision. Treatment is given for 1–2 weeks after the resolution of symptoms. The duration of additional therapy should be guided by frequent ophthalmologic examinations. Pyrimethamine can cause gastrointestinal upset, leukopenia, thrombocytopenia, and rarely, agranulocytosis; weekly complete blood counts should be checked while on therapy.

A year of treatment is recommended for all congenitally infected infants. Children treated with pyrimethamine (loading dose 2 mg/kg daily for 2 days followed by 1 mg/kg daily for 6 months followed by 1 mg/kg every Monday, Wednesday, and Friday for 6 months) plus sulfadiazine (100 mg/kg divided twice daily for 12 months) plus leucovorin (10 mg 3 times a week) have better neurodevelopmental and visual outcomes than historical controls. While on therapy, infants should be monitored for bone marrow toxicity.

In primary maternal infection during the first 18 weeks of pregnancy, spiramycin is recommended to attempt to prevent fetal infection. Spiramycin does not cross the placenta, so does not treat fetal infection. If fetal infection has been documented or if primary maternal infection occurs after the first 18 weeks of pregnancy, pyrimethamine, sulfadiazine, and leucovorin are recommended. Pyrimethamine is teratogenic and should not be used before 18 weeks of gestation.

http://www.cdc.gov/parasites/toxoplasmosis/.
1. Amebiasis

Amebiasis is defined as an infection with *Entamoeba histolytica* regardless of symptoms. This parasite is found worldwide, but has a particularly high prevalence in areas with poor sanitation and socioeconomic conditions. In the United States, infections are seen in travelers to and emigrants from endemic areas. Transmission is usually fecal-oral. Infections with two other *Entamoeba* species, *E dispar* and *E moshkovskii*, are morphologically indistinguishable from *E histolytica*. Infections with these species are approximately 10 times more common than infection with *E histolytica*, but are not thought to cause human disease.

**Clinical Findings**

**A. Symptoms and Signs**

Patients with intestinal amebiasis can have asymptomatic cyst passage, or be symptomatic with acute amebic proctocolitis, chronic nondysenteric colitis, or ameboma. Because all *E dispar* and *E moshkovskii* infections and up to 90% of *E histolytica* infections are asymptomatic, carriage is the most common manifestation of amebiasis. Patients with acute amebic colitis typically have a 1- to 2-week history of loose stools containing blood and mucus, abdominal pain, and tenesmus. A minority of patients are febrile or dehydrated. Abdominal examination may reveal pain over the lower abdomen.

Fulminant colitis is an unusual complication of amebic dysentery that is associated with a grave prognosis (>50% mortality), and is characterized by severe bloody diarrhea, fever, and diffuse abdominal pain. Children younger than age 2 years are at increased risk for this condition. Chronic amebic colitis causes recurrent episodes of bloody diarrhea over a period of years and is clinically indistinguishable from idiopathic inflammatory bowel disease. An ameboma is a localized amebic infection, usually in the cecum or ascending colon, which presents as a painful abdominal mass.

The most common complications of intestinal amebiasis are intestinal perforation, toxic megacolon, and peritonitis. Perianal ulcers, a less common complication, are painful, punched-out lesions that usually respond to medical therapy. Infrequently, colonic strictures may develop following colitis.

Extraintestinal amebiasis can result in liver, lung, and cerebral abscesses, and rarely genitourinary disease. Patients with amebic liver abscess, the most common form of extraintestinal amebiasis, typically present with acute fever and right upper quadrant tenderness. The pain may be dull, pleuritic, or referred to the right shoulder. Physical examination reveals liver enlargement in less than 50% of affected patients. Some patients have a subacute presentation lasting 2 weeks to 6 months. In these patients, hepatomegaly, anemia, and weight loss are common findings, and fever is less common. Jaundice and diarrhea are rarely associated with an amebic liver abscess. In children with fever of unknown origin who live in, or travel to, endemic areas, amebic liver abscess should be considered in the differential diagnosis.

The most common complication of amebic liver abscess is pleuropulmonary amebiasis due to rupture of a right liver lobe abscess. Lung abscesses may occur from hematogenous spread. Cough, dyspnea, and pleuritic pain can be caused by the serous pleural effusions and atelectasis that frequently accompany amebic liver abscesses. Rupture of hepatic abscesses can lead to peritonitis and more rarely to pericarditis. Amebic brain abscess is an infrequent manifestation.

**B. Diagnostic Findings**

The differential diagnosis of acute amebic colitis includes bacterial (eg, *Salmonella* spp, *Shigella* spp, *E coli* spp, *Campylobacter* spp), parasitic (eg, *Schistosoma mansoni, Balantidium coli*), and noninfectious (eg, inflammatory bowel disease, diverticulitis, ischemic colitis) causes of dysentery. Chronic amebic colitis has to be distinguished from inflammatory bowel disease and *Cyclospora*. Occult blood is present in virtually all cases of amebic colitis and can be used as an inexpensive screening test. Fecal leukocytes are uncommon.

Intestinal amebiasis can be presumptively diagnosed by detecting the parasite on stool examination or mucosal biopsy. However, *E histolytica* is morphologically identical
to nonpathogenic *E dispar* and *E moshkovskii* and cannot be easily differentiated by microscopy. The presence of trophozoites with ingested red blood cells in feces is more suggestive of pathogenic *E histolytica* infection. Ideally, a wet mount preparation of the stool should be examined within 20 minutes after collection to detect motile trophozoites. Otherwise, specimens should be fixed with polyvinyl alcohol or refrigerated to avoid disintegration of the trophozoites. The antigen detection test for stool is very sensitive and more specific, because it detects *E histolytica*-specific antigens that do not cross-react with *E dispar*. Colonoscopy and biopsy are most helpful in diagnosing amebic colitis when stool samples lack ova or parasites. Barium studies are contraindicated for patients with suspected acute amebic colitis because of the risk of perforation.

The presence of antibodies against *E histolytica* can differentiate *E histolytica* from *E dispar* infections. Specific antibody is induced by both intestinal and extraintestinal invasive amebiasis. ELISA assays are positive in approximately 95% of patients with extraintestinal amebiasis, 70% with intestinal *E histolytica* disease, and 10% of asymptomatic patients shedding *E histolytica* cysts. However, these antibodies persist for years, and a positive result does not distinguish between acute and past infection, but are useful in a traveler from a nonendemic area who is returning from a trip to an endemic area. Ultrasonographic examination and CT are sensitive techniques to detect hepatic abscesses and can be used to guide fine-needle aspiration to obtain specimens for definitive diagnosis. Because an amebic abscess may take up to 2 years to completely resolve on CT scans, imaging techniques are not recommended for therapeutic evaluation. PCR-based testing has the highest sensitivity and specificity for the diagnosis of *E histolytica*, but is only available in certain research and reference laboratories.

### Prevention & Treatment

Travelers to endemic areas need to follow the precautions for preventing enteric infections—drink bottled or boiled water and eat cooked or peeled vegetables and fruits.

Treatment of amebic infection is complex because different agents are required for eradicating the parasite from the bowel or tissue (Table 43–5). Whether treatment of asymptomatic cyst passers is indicated is a controversial issue. The prevalent opinion is that asymptomatic infection with *E histolytica*, as evidenced by amebic cysts in the stool and a positive serologic test, should be treated in nonendemic areas. If serologic tests are negative, the cysts are more likely to represent infection with the nonpathogenic *E dispar*, which does not require treatment.

Asymptomatic *E histolytica* cyst excreters may be treated with paromomycin, a nonabsorbable intraluminal amebicide. Diloxanide and iodoquinol are alternative intraluminal agents. Metronidazole is not effective against cysts.

**Table 43-5. Treatment of amebiasis.**

</tbody>
</table>

*Diloxanide furoate is available from the CDC Drug Service: (404) 639–3670.*

*Treatment should be followed by iodoquinol or paromomycin.*

*Not marketed in the United States; higher dosage.*

Patients with symptomatic intestinal amebiasis or extraintestinal disease require treatment with an absorbable agent, such as metronidazole or tinidazole, followed by an intraluminal agent. Metronidazole has a disulfiram-like effect and should be avoided in patients receiving ethanol-containing medications. Tinidazole, a more potent nitroimidazole against amebic infection, can be used for shorter treatment courses and is well tolerated in children. Treatment of invasive amebiasis should always be followed with an intraluminal cysticidal agent, even if the stool examination is negative. Metronidazole and paromomycin should not be given concurrently, because the diarrhea that is a common side effect of paromomycin may make it difficult to assess response to therapy. In most patients with amebic liver abscess, aspiration is unnecessary and does not speed recovery. Patients with large, thin-walled hepatic abscesses may need therapeutic aspiration to avoid abscess rupture. Drainage may also be considered when response to medical therapy is inadequate.

2. Giardiasis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Chronic relapsing diarrhea, flatulence, bloating, anorexia, poor weight gain.
- No fever or hematochezia.
- Detection of trophozoites, cysts, or Giardia antigens in stool.

General Considerations

Giardiasis, caused by Giardia intestinalis (formerly Giardia lamblia), is the most common intestinal protozoal infection in children in the United States and in most of the world. The infection is classically associated with drinking contaminated water, either in rural areas or in areas with faulty purification systems. Even ostensibly clean urban water supplies can be contaminated intermittently, and infection has been acquired in swimming pools. Fecal-oral contamination allows person-to-person spread. Day care centers are a major source of infection, with an incidence of up to 50% reported in some centers. No symptoms occur in 25% of infected persons, facilitating spread to household contacts. Food-borne outbreaks also occur. Although infection is rare in neonates, giardiasis may occur at any age.

Clinical Findings

A. Symptoms and Signs

Giardia infection is followed by either asymptomatic cyst passage, acute self-limited diarrhea, or a chronic syndrome of diarrhea, malabsorption, and weight loss. Acute diarrhea occurs 1–2 weeks after infection and is characterized by abrupt onset of diarrhea with greasy, malodorous stools; malaise; flatulence; bloating; and nausea. Fever and vomiting are unusual. The disease has a protracted course (>1 week) and frequently leads to weight loss. Giardiasis can be a self-limited infection in some patients, and in others cause chronic symptoms. Patients who develop chronic diarrhea complain of profound malaise, lassitude, headache, and diffuse abdominal pain in association with bouts of diarrhea—most typically foul-smelling, greasy stools—intercalated with periods of constipation or normal bowel habits. This syndrome can persist for months until specific therapy is administered or until it subsides spontaneously. Chronic diarrhea frequently leads to malabsorption, steatorrhea, vitamins A and B₁₂ deficiencies, and disaccharidase depletion. Lactose intolerance, which develops in 20%–40% of patients can persist for several weeks after treatment, and needs to be differentiated from relapsing giardiasis or reinfection.

B. Laboratory Findings

Giardia antigen detection by means of ELISAs, nonenzymatic immunoassays, and direct fluorescence antibody tests are the standard diagnostic tests in the United States. They have a more rapid return of results, and are more sensitive and specific than stool ova and parasite examination. In resource-poor areas without access to antigen tests, the diagnosis of giardiasis can be made by finding the parasite in stool. For ova and parasite examination, a fresh stool provides the best results. Liquid stools have the highest yield of trophozoites, which are more readily found on wet mounts. With semiformed stools, the examiner should look for cysts in fresh or fixed specimens, preferably using a concentration technique. When these techniques are applied carefully, one examination has a sensitivity of 50%–70%; three examinations increase the sensitivity to 90%. With a careful stool ova and parasite examination or with the use of a new antigen test, direct sampling of duodenal aspirates or biopsy, which was utilized in the past, is now restricted to particularly difficult cases.

Prevention

The prevention of giardiasis requires proper treatment of water supplies and interruption of person-to-person transmission. Where water might be contaminated, travelers, campers, and hikers should use methods to make water safe for drinking. Boiling is the most reliable method; the necessary time of boiling (1 minute at sea level) will depend on the altitude. Chemical disinfection with iodine or chlorine and filtration are alternative methods of water treatment.

Interrupting fecal-oral transmission requires strict hand washing. However, outbreaks of diarrhea in day care centers might be particularly difficult to eradicate. Reinforcing hand washing and treating the disease in both symptomatic and asymptomatic carriers may be necessary.

Treatment

Metronidazole, tinidazole, and nitazoxanide are the drugs of choice for treatment of giardiasis. When given at 5 mg/kg (up to 250 mg) three times a day for 5–7 days, metronidazole has 80%–95% efficacy. The drug is well tolerated in children. Tinidazole has an efficacy approaching 90% when given as a single dose of 50 mg/kg (up to 2 g). Nitazoxanide is available in liquid formulation and requires only 3 days of treatment. Recommended doses are 100 mg (5 mL) every 12 hours for children 12–47 months of age, 200 mg (10 mL) every 12 hours for 4- to 11-year-olds, and 500 mg every 12 hours for children 12 years or older. Furazolidone is sometimes used in children because it is available in suspension.
Administered at 1.5 mg/kg (up to 100 mg) four times daily for 7–10 days, it has only 80% efficacy. Furazolidone may cause gastrointestinal side effects, turn urine red, and cause mild hemolysis in patients with G6PD deficiency. For patients who do not respond to therapy, or are re-infected, a second course with the same drug or switching to another drug is equally effective. In cases of repeated treatment failure, albendazole (400 mg/d for 5–10 days), although not specifically recommended in the United States for the treatment of giardiasis, is an effective option.

3. Cryptosporidiosis

Cryptosporidia are intracellular protozoa that gained importance because they cause severe and devastating diarrhea in patients with acquired immunodeficiency syndrome (AIDS) and in other immunodeficient persons. This ubiquitous parasite infects and reproduces in the epithelial cell lining of the digestive and respiratory tracts of humans and most other vertebrate animals. Humans acquire the infection from contaminated drinking water, recreation water sources (including swimming pools, fountains, and lake water), or from close contact with infected humans or animals. Cryptosporidia are the leading cause of recreational water-associated outbreaks in the United States. Petting zoos and day care centers have been other sources of Cryptosporidia outbreaks. Most human infections are caused by *C parvum* or *C hominis*, although other species have been reported to cause human disease.

Clinical Findings

A. Symptoms and Signs

Immunocompetent persons infected with *Cryptosporidium* spp usually develop self-limited diarrhea (2–26 days) with or without abdominal cramps. Diarrhea can be mild and intermittent or continuous, watery, and voluminous. Low-grade fever, nausea, vomiting, loss of appetite, and malaise may accompany the diarrhea. Children younger than age 2 years are more susceptible to infection than older children. Immunocompromised patients (either cellular or humoral deficiency) tend to develop a severe, prolonged, chronic diarrhea which can often result in severe malnutrition, and subsides only after the immunodeficiency is corrected. Other clinical manifestations associated with cryptosporidiosis in immunocompromised hosts include cholecystitis, pancreatitis, hepatitis, biliary tree involvement, and respiratory symptoms.

B. Laboratory Findings

Visualization of *Cryptosporidium* oocysts in the stool is diagnostic. Direct immunofluorescent antibody (DFA) of stool is the test of choice for visualizing oocysts. Oocysts can also be visualized with a modified Kinyoun acid-fast stain on concentrated stool. ELISA and point-of-care rapid tests are commercially available, but should be confirmed by microscopy.

Prevention & Treatment

Prevention of *Cryptosporidium* infection is limited by oocyst resistance to some of the standard water purification procedures and to common disinfectants. Enteric precautions are recommended for infected persons. Boiled or bottled drinking water may be considered for those at high risk for developing chronic infection (eg, inadequately treated patients with AIDS).

Immunocompetent patients and those with temporary immunodeficiencies respond to treatment with nitazoxanide, antidiarrheal agents, and hydration. Immunocompromised patients usually require more intense supportive care with parenteral nutrition in addition to hydration and nonspecific antidiarrheal agents. Octreotide acetate, a synthetic analogue of somatostatin that inhibits secretory diarrhea, has been associated with symptomatic improvement but not with parasitologic cure. Nitazoxanide for 3 days is the treatment of choice; recommended doses are 100 mg (5 mL) every 12 hours for children 12–47 months of age, 200 mg (10 mL) every 12 hours for 4- to 11-year-olds, and 500 mg every 12 hours for children 12 years or older. For patients with advanced AIDS, antiparasitic therapy alone has not proven efficacious. Institution of effective anti-retroviral therapy results in elimination of symptomatic cryptosporidiosis.

4. Cyclosporiasis

*Cyclospora* spp are ubiquitous coccidian parasites that infect both humans and a variety of animals worldwide. *Cyclospora cayetanensis* is the only species known to infect humans. Cyclosporiasis is seen in three main epidemiologic settings: sporadic cases in endemic areas (particularly Haiti, Guatemala, Peru, and Nepal), travelers to endemic areas, and in food- or water-borne outbreaks in nonendemic areas.
particularly in relation to importation of fresh produce. The incubation period is approximately 7 days (range 2–14 days). Infection may be asymptomatic, cause mild to moderate self-limiting diarrhea, or cause protracted or severe diarrhea. In the immunocompetent host, diarrhea usually lasts 10–25 days but may be followed by a relapsing pattern that can last several months. Diarrhea (5–15 movements per day) is usually watery, sometimes explosive, and often accompanied by nausea, vomiting, abdominal cramping, and bloating. Profound fatigue, anorexia, and myalgias have been reported. The infection can be unusually severe in immunocompromised patients, especially those with HIV/AIDS. Although the illness is self-limited, it may last for several weeks. Diagnosis is based on finding oocysts 8–10 mm in diameter on examination of stool specimens stained with acid-fast stain. PCR of stool is available at the CDC and some reference laboratories. The treatment of choice is trimethoprim-sulfamethoxazole for 7 days.

5. Free-Living Amoebas

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Acute meningoencephalitis: fever, headache, meningismus, acute mental deterioration.
▶ Swimming in warm, freshwater in an endemic area.
▶ Chronic granulomatous encephalitis: insidious onset of focal neurologic deficits.
▶ Keratitis: pain, photophobia, conjunctivitis, blurred vision.

General Considerations

Infections with free-living amoebas are uncommon. Naegleria species, Acanthamoeba species, and Balamuthia amoebas have been associated with human disease, primarily infections of the central nervous system. Acute meningoencephalitis, caused by Naegleria fowleri, occurs mostly in children and young adults. Patients present with abrupt fever, headache, nausea and vomiting, disturbances in smell and taste, meningismus, and decreased mental status a few days to 2 weeks after exposure. N fowleri is found in warm freshwater and moist soil. Infection is often associated with swimming in warm freshwater lakes and using contaminated tap water for sinus irrigation. CNS invasion occurs after nasal inoculation of N fowleri which travel along the olfactory nerves via the cribiform plate to the brain. The disease is rapidly progressive and nearly universally fatal within a week of symptom onset.

Chronic granulomatous encephalitis, caused by Acanthamoeba or Balamuthia, can occur in immunocompetent patients, but occurs more commonly in immunocompromised patients. There is no association with freshwater swimming. This disease has an insidious onset of focal neurologic deficits, and approximately 50% of patients present with headache. Skin, sinus, or lung infections with Acanthamoeba precede many of the CNS infections and may still be present at the onset of neurologic disease. The granulomatous encephalitis progresses to fatal outcome over a period of weeks to months (average 6 weeks).

Acanthamoeba keratitis is a corneal infection associated with minor trauma or use of soft contact lenses in otherwise healthy persons. Clinical findings of Acanthamoeba keratitis include radial keratoneuritis and stromal ring infiltrate. Amebic keratitis usually follows an indolent course and initially may resemble herpes simplex or bacterial keratitis; delay in diagnosis is associated with worse outcomes.

Clinical Findings & Differential Diagnosis

Amebic encephalitis should be included in the differential diagnosis of acute meningoencephalitis in children with a history of recent freshwater swimming. The CSF is usually hemorrhagic, with leukocyte counts that may be normal early in the disease but later range from 400 to 2600/mL with neutrophil predominance, low to normal glucose, and elevated protein. The etiologic diagnosis relies on finding trophozoites on a wet mount of the CSF. Immunofluorescent and PCR-based diagnostic assays are available through the CDC.

Granulomatous encephalitis is diagnosed by brain biopsy of CT-identified nonenhancing lucent areas. The CSF of these patients is usually nondiagnostic with a lymphocytic pleocytosis, mild to severe elevation of protein (> 1000 mg/dL), and normal or low glucose. Acanthamoeba and Balamuthia amoebas have only rarely been found in the CSF; however, they can be visualized in brain biopsies or grown from brain or other infected tissues. Immunofluorescent and PCR-based diagnostic assays are available through the CDC.

Acanthamoeba keratitis is diagnosed by finding the trophozoites in corneal scrapings or by isolating the parasite from corneal specimens or contact lens cultures.

Prevention

Because primary amebic meningitis occurs infrequently, active surveillance of lakes for N fowleri is not warranted. However, in the presence of a documented case, it is advisable to close the implicated lake to swimming. Sterile or boiled water should be used for sinus irrigation. Acanthamoeba
keratitis can be prevented by heat disinfection of contact lenses, by storage of lenses in sterile solutions, and by not wearing lenses when swimming in freshwater or showering.

**Treatment**

Treatment of acute amebic meningoencephalitis caused by *N. fowleri* should be attempted with high-dose intravenous amphotericin B with the possible addition of miconazole and rifampin. Azithromycin has in vitro and in vivo activity against *Naegleria* and may be tried as an adjuvant. Successful treatment of *Balamuthia* encephalitis has been reported using a combination of flucytosine, pentamidine, fluconazole, sulfadiazine, and a macrolide. *Acanthamoeba* encephalitis should be treated with a combination of pentamidine, an azole compound, flucytosine, and sulfadiazine.

*Acanthamoeba* keratitis responds well to surgical debridement followed by 3–4 weeks of topical 1% miconazole; 0.1% propamidine isethionate; and polymyxin B sulfate, neomycin, and bacitracin (Neosporin).

http://www.cdc.gov/parasites/naegleria/
http://www.cdc.gov/parasites/balamuthia/
http://www.cdc.gov/parasites/acantamoeba/

**TRICHOMONIASIS**

*Trichomonas vaginalis* infection is discussed in Chapter 44.

**METAZOAL INFECTIONS**

**NEMATODE INFECTIONS**

1. **Enterobiasis (Pinworms)**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Anal pruritus.
- Worms in the stool or eggs on perianal skin.

**General Considerations**

This worldwide infection is caused by *Enterobius vermicularis*. The adult worms are about 5–10 mm long and live in the colon; females deposit eggs on the perianal area, primarily at night, which cause intense pruritus. Scratching contaminates the fingers and allows transmission back to the host (autoinfection) or to contacts through fecal-oral spread.

**Clinical Findings**

A. **Symptoms and Signs**

Although blamed for many types of symptoms, pinworms have only definitely been associated with localized pruritus. Adult worms may migrate within the colon or up the urethra or vagina in girls. They can be found within the bowel wall, in the lumen of the appendix (usually an incidental finding by the pathologist), in the bladder, and even in the peritoneal cavity of girls. The granulomatous reaction that may be present around these ectopic worms is usually asymptomatic. Worm eradication may correspond with the cure of recurrent urinary tract infections in some young girls.

B. **Laboratory Findings**

The usual diagnostic test consists of pressing a piece of transparent tape on the child’s anus in the morning prior to bathing, then placing it on a drop of xylene on a slide. Microscopic examination under low power usually demonstrates the ova. Occasionally, eggs or adult worms are seen in fecal specimens. Parents may also visualize adult worms in the perianal region, often at nighttime while the child is asleep.

**Differential Diagnosis**

Nonspecific irritation or vaginitis, streptococcal perianal cellulitis (usually painful with marked erythema), and vaginal or urinary bacterial infections may at times resemble pinworm infection, although the symptoms of pinworms are often so suggestive that a therapeutic trial is justified without a confirmed diagnosis.

**Treatment**

A. **Specific Measures**

Treat all household members at the same time to prevent reinfections. Because the drugs are not active against the eggs, therapy should be repeated after 2 weeks to kill the recently hatched adults.

Pyrantel pamoate, available without a prescription, is given as a single dose (11 mg/kg; maximum 1 g); it is safe and very effective. Albendazole (400 mg or 200 mg in children 1–2 years of age) or mebendazole (100 mg) in a single dose is also highly effective for all ages (though not approved by the US FDA).
B. General Measures

Personal hygiene must be emphasized. Nails should be kept short and clean. Children should wear undergarments in bed to diminish contamination of fingers; bedclothes should be laundered frequently; infected persons should bathe in the morning, thereby removing a large proportion of eggs. Although eggs may be widely dispersed in the house and multiple family members infected, the disease is mild and treatable.

http://www.cdc.gov/parasites/pinworm/.

2. Ascariasis

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Abdominal cramps and discomfort.
- Large, white or reddish, round worms, or ova in the feces.

**General Considerations**

Together with the whipworm and hookworms (see below), *Ascaris* comprises the group of “soil-transmitted helminths.” These parasites cause human infection through contact with eggs or larvae that thrive in the moist soil of the tropics and subtropics. Worldwide, more than a billion people are infected with at least one of these parasites, and, especially in less developed countries, it is not uncommon for children to be chronically infected with all three worms. These parasites are strongly associated with acute poverty and lack of clean water and sanitation. Children infected with these worms are at increased risk for malnutrition, stunted growth, intellectual retardation, and cognitive and education deficits. Together, the soil-transmitted helminths are one of the world’s most important causes of physical and intellectual growth retardation.

*Ascaris lumbricoides* is a worldwide human parasite. Ova passed by carriers may remain viable for months under the proper soil conditions. The ova contaminate food or fingers and are subsequently ingested by a new host. The larvae hatch, penetrate the intestinal wall, enter the venous system, reach the alveoli, are coughed up, and return to the small intestine, where they mature. The female lays thousands of eggs daily.

**Clinical Findings**

**A. Symptoms and Signs**

The majority of infections with *A lumbricoides* are asymptomatic, although moderate to heavy infections are associated with abdominal pain, weight loss, anorexia, diarrhea, and vomiting, and may lead to malnutrition. During the larval migratory phase, an acute transient eosinophilic pneumonitis (Löffler syndrome) may occur. Acute intestinal obstruction has been associated with heavy infections, which is more common in children due to their smaller intestinal diameter and their higher worm burden. Rarely, worm migration can cause peritonitis or appendicitis, secondary to intestinal wall perforation, and common bile duct obstruction, resulting in biliary colic, cholangitis, or pancreatitis.

**B. Laboratory Findings**

The diagnosis is made by observing the large roundworms (1.5–4 cm) in the stool or by microscopic detection of the ova.

**Treatment**

Because the adult worms live less than a year, asymptomatic infection need not be treated. Mebendazole (100 mg twice a day for 3 days or 500 mg once), pyrantel pamoate (a single dose of 11 mg/kg; maximum 1 g), and albendazole (400 mg in a single dose, or 200 mg in children 1–2 years of age) are highly and equally effective. In cases of intestinal or biliary obstruction, piperazine (150 mg/kg initially, followed by six doses of 65 mg/kg every 12 hours by nasogastric tube) is recommended because it paralyzes the worms and helps relieve obstruction. However, surgical removal is occasionally required.

http://www.who.int/intestinal_worms/.
http://www.cdc.gov/parasites/sth/.

3. Trichuriasis (Whipworm)

*Trichuris trichiura* is a widespread human and animal parasite common in children living in warm, humid areas conducive to survival of the ova. Ingested infective eggs hatch in the upper small intestine. The adult worms live in the cecum and colon; the ova are passed and become infectious after several weeks in the soil. Unlike *Ascaris*, *Trichuris* does not have a migratory tissue phase. Symptoms are not present unless the infection is severe, in which case pain, diarrhea, iron deficient anemia, and mild abdominal distention are present. Massive infections may also cause rectal prolapse and dysentery. Detection of the characteristic barrel-shaped ova in the feces confirms the diagnosis. Adult worms may be seen in the prolapsed rectum or at
proctoscopy; their thin heads are buried in the mucosa, and the thicker posterior portions protrude. Mild to moderate eosinophilia may be present.

Treatment of trichuriasis with currently available anthelminthic agents is unsatisfactory. Nevertheless, mebendazole (100 mg orally twice a day for 3 days) or albendazole (400 mg in a single dose for 3 days, or 200 mg in children 1–2 years of age) tends to improve gastrointestinal symptoms.

http://www.who.int/intestinal_worms/.
http://www.cdc.gov/parasites/sth/.

4. Hookworm

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▸ Iron-deficiency anemia.
▸ Abdominal discomfort, weight loss.
▸ Ova in the feces.

▸ General Considerations

The common human hookworms are Ancylostoma duodenumale and Necator americanus. Both are widespread in the tropics and subtropics, with an estimated 600–700 million people infected worldwide. The larger A duodenumale is more pathogenic because it consumes more blood, up to 0.5 mL per worm per day.

The adults live in the jejunum. Eggs are passed in the feces and develop and hatch into infective larvae in warm, damp soil within 2 weeks. The larvae penetrate human skin on contact, enter the blood, reach the alveoli, are coughed up and swallowed, and develop into adults in the intestine. The adult worms attach with their mouth parts to the mucosa, from which they suck blood. Blood loss is the major sequela of infection. Infection rates reach 90% in areas without sanitation.

Ancylostoma braziliense and Ancylostoma caninum (the dog and cat hookworm) cause creeping eruption (cutaneous larva migrans). Larvae produce pruritic, reddish papules at the site of skin entry and an intensely pruritic, serpiginous tracks or bullae are formed as they migrate through the skin. Larval can move up to a few centimeters a day and activity can continue for several weeks, but eventually the rash is self-limiting. An advancing, intensely pruritic, serpiginous tunnel in the skin is pathognomonic. Cutaneous larva migrans is a disease of children and others who come in contact with soil contaminated with cat and dog feces. In the United States, the disease is most prevalent in the Southeast. Most cases in the United States are imported by travelers returning from tropical and subtropical areas.

▸ Clinical Findings

A. Symptoms and Signs

Patients with hookworm infection usually are asymptomatic or have complaints of diarrhea. Chronic hookworm infection leads to blood loss and iron deficiency anemia. Heavy infection can cause hypoproteinemia with edema. Chronic hookworm infection in children may lead to growth delay, deficits in cognition, and developmental delay. The larvae usually penetrate the skin of the feet and cause a stinging or burning sensation, followed by an intense local itching (ground itch) and a papulovesicular rash that may persist for 1–2 weeks. Pneumonitis associated with migrating larvae is uncommon and usually mild, except during heavy infections. Colicky abdominal pain, nausea, and/or diarrhea and marked eosinophilia may be observed.

B. Laboratory Findings

The large ova of both species of hookworm are found in feces and are indistinguishable. Microcytic anemia, hypoalbuminemia, eosinophilia, and hematochezia occur in severe cases.

▸ Prevention

Fecal contamination of soil and skin contact with potentially contaminated soil should be avoided.

▸ Treatment

A. Specific Measures

Albendazole (400 mg orally in a single dose, or 200 mg in children 1–2 years of age) is significantly more efficacious than mebendazole or pyrantel pamoate, and is considered the drug of choice for treatment of hookworm infections. Mebendazole (100 mg orally twice a day for 3 days) and pyrantel pamoate (11 mg/kg, to a maximum of 1 g, daily for 3 days) are second-line options.

B. General Measures

Iron therapy may be as important as worm eradication.

▸ Prognosis

The outcome after therapy is excellent, but reinfection is common in endemic areas.
5. Strongyloidiasis

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Abdominal pain, diarrhea.
- Eosinophilia.
- Larvae in stools and duodenal aspirates.
- Serum antibodies.

**General Considerations**

*Strongyloides stercoralis* is unique in having both parasitic and free-living forms; the latter can survive in the soil for several generations. The parasite is found in most tropical and subtropical regions of the world. The adults live in the submucosal tissue of the duodenum and occasionally elsewhere in the intestines. Eggs deposited in the mucosa hatch rapidly; the first-stage (rhabditiform) larvae, therefore, are the predominant form found in duodenal aspirates and feces. The larvae mature rapidly to the tissue-penetrating filariform stage and initiate internal autoinfection. The filariform larvae also persist in soil and can penetrate the skin of another host, subsequently migrating into veins and pulmonary alveoli, reaching the intestine when coughed up and swallowed.

Older children and adults are infected more often than are young children. Even low worm burden can result in significant clinical symptoms. Immunosuppressed patients may develop fatal disseminated strongyloidiasis, known as the hyperinfection syndrome. Autoinfection can result in persistent infection for decades.

**Clinical Findings**

**A. Symptoms and Signs**

Chronic *S. stercoralis* infections can be asymptomatic or cause cutaneous, gastrointestinal, and/or pulmonary symptoms. At the site of skin penetration, a pruritic rash may occur. Large numbers of migrating larvae can cause wheezing, cough, shortness of breath, and hemoptysis. Although one-third of intestinal infections are asymptomatic, the most prominent features of strongyloidiasis include abdominal pain, distention, diarrhea, vomiting, and occasionally malabsorption.

Patients with cellular immunodeficiencies and those on corticosteroids or chemotherapy may develop disseminated infection, involving the intestine, the lungs, and the meninges. Gram-negative sepsis may complicate disseminated strongyloidiasis.

**B. Laboratory Findings**

There is no gold standard for diagnosis, which can be difficult because of low parasite load and irregular larval output. Finding larvae in the feces, duodenal aspirates, or sputum is diagnostic. IgG antibodies measured by ELISA or immunoblot are relatively sensitive (83%–93%). The presence of specific antibody, however, does not distinguish between past and present infection and *Strongyloides* antibody assays can cross-react with other helminth infections. Marked eosinophilia is common. Because the rate of detection of *Strongyloides* larvae in a single fecal sample is low (~25%), all patients who have visited an endemic area and present with GI symptoms should be evaluated with three serial stool samples (for ova and parasites), and serology (ELISA) for *S. stercoralis* should be performed. Patients with pulmonary symptoms with suspected strongyloides infection should have sputum samples evaluated for the detection of *S. stercoralis*.

**Differential Diagnosis**

Strongyloidiasis should be differentiated from peptic disease, celiac disease, regional or tuberculous enteritis, and hookworm infections. The pulmonary phase may mimic asthma or bronchopneumonia. Patients with severe infection can present with an acute abdomen.

**Prevention & Treatment**

Ivermectin (two doses of 0.2 mg/kg given 1–14 days apart) is the drug of choice. Tiabendazole at a dose of 25 mg/kg orally twice orally twice a day for three days is an alternative therapy. Albendazole has a much lower efficacy. Relapses are common. In the hyperinfection syndrome, 1–3 weeks of therapy with ivermectin may be necessary and multiple follow-up stool studies for 2 weeks after therapy are indicated to ensure clearance of larvae. Patients from endemic areas should be tested for specific antibodies and receive treatment before undergoing immunosuppression.
ChAPTER 43

http://www.cdc.gov/parasites/strongyloides/

6. Visceral Larva Migrans (Toxocariasis)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Visceral involvement, including hepatomegaly, marked eosinophilia, and anemia.
- Posterior or peripheral ocular inflammatory mass.
- Elevated antibody titers in serum or aqueous fluid; demonstration of Toxocara larvae in biopsy specimen.

General Considerations

Visceral larva migrans is a worldwide disease. The agent is the cosmopolitan intestinal ascarid of dogs and cats, Toxocara canis or Toxocara cati. The eggs passed by infected animals contaminate parks and other areas that young children frequent. Children with pica are at increased risk. In the United States, seropositivity ranges from 2.8% in unselected populations to 23% in southern states to 54% in rural areas. Ingested eggs hatch and penetrate the intestinal wall, then migrate to the liver. Most of the larvae are retained in the liver, but some may pass through the organ reaching the lungs, eyes, muscles, and/or the CNS, where they die and incite a granulomatous inflammatory reaction.

Clinical Findings

A. Visceral Larva Migrans

Toxocariasis is usually asymptomatic, but young children (aged 1–5 years) sometimes present with anorexia, fever, fatigue, pallor, abdominal pain and distention, nausea, vomiting, and cough. Hepatomegaly is common, splenomegaly is unusual, and adenopathy is absent. Lung involvement, usually asymptomatic, can be demonstrated readily by radiologic examination. Seizures are common, but more severe neurologic abnormalities are infrequent. Eosinophilia with leukocytosis, anemia, and elevated liver function tests are typical. ELISA is sensitive, specific, and useful in confirming the clinical diagnosis. Most patients recover spontaneously, but disease may last up to 6 months.

B. Ocular Larva Migrans

This condition occurs in older children and adults who present with a unilateral posterior or peripheral inflammatory eye mass. History of visceral larva migrans and eosinophilia are typically absent. Anti-Toxocara antibody titers are low in the serum and high in vitreous and aqueous fluids.

C. Diagnostic Findings

Hypergammaglobulinemia and elevated isohemagglutinins sometimes result from cross-reactivity between Toxocara antigens and human group A and B blood antigens. The diagnosis is confirmed by finding larvae in granulomatous lesions. High ELISA serology and the exclusion of other causes of hypereosinophilia provide a presumptive diagnosis in typical cases.

Differential Diagnosis

Diseases associated with hypereosinophilia must be considered. These include trichinosis (enlarged liver not common; muscle tenderness common), eosinophilic leukemia (rare in children; eosinophils are abnormal in appearance), collagen-vascular disease (those associated with eosinophilia are rare in young children), strongyloidiasis (no organomegaly; enteric symptoms are common), early ascariasis, tropical eosinophilia (occurring mainly in India), allergies, and hypersensitivity syndromes.

Prevention & Treatment

A. Specific Measures

The clinical benefit of specific anthelmintic therapy is not defined. Treatment with albendazole (400 mg twice a day for 5 days) or mebendazole (100–200 mg twice a day for 5 days) is indicated for severe complications involving the brain, lung, or heart.

B. General Measures

Treating any cause of pica, such as iron deficiency, is important. Corticosteroids are used to treat marked inflammation of lungs, eyes, or other organs. Pets should be dewormed routinely. Other children in the household may be infected. Mild eosinophilia and positive serologic tests may be the only clue to their infection. Therapy is not necessary for these individuals.

7. Trichinosis

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Vomiting, diarrhea, and abdominal pain within 1 week of eating infected meat.
- Fever, periorbital edema, myalgia, and marked eosinophilia.

**General Considerations**

*Trichinella* are small roundworms that infest hogs and several other meat-eating animals. Currently, there are eight recognized *Trichinella* species, with *Trichinella spiralis* being the most commonly recognized and most adapted to domestic and wild swine. The most important source of human infection worldwide is the domestic pig, but in Europe meat from wild boars and horses caused several prominent outbreaks. The human cycle begins with ingestion of viable larvae in undercooked meat. In the intestine, the larvae develop into adult worms that mate and produce hundreds of larvae. The larvae enter the bloodstream and migrate to the striated muscle where they continue to grow and eventually encyst. Symptoms are caused by the inflammatory response in the intestines or muscle.

**Clinical Findings**

**A. Symptoms and Signs**

Most infections are asymptomatic. The severity of clinical disease is strongly correlated with the number of ingested larvae. Infection can be divided into two phases: an intestinal phase and a muscular (or systemic) phase. The initial bowel penetration may cause fever, headache, chills, and gastrointestinal complaints within 1 week after ingestion of contaminated meat. This may progress to the classic myopathic form, which consists of fever, eyelid or facial edema, myalgia, and weakness. Complications, including myocarditis, thromboembolic disease, and encephalitis, occasionally occur. The leading pathologic process of trichinellosis is vasculitis, which can be manifest as a maculopapular exanthem, subungual bleeding, conjunctivitis and subconjunctival hemorrhages, headaches, dry cough, and painful movement of the eye muscles. Severe cerebral involvement or myocarditis can be fatal. Symptoms usually peak after 2–3 weeks but may last for months. Children typically have milder clinical and laboratory findings than adults.

**B. Diagnosis**

The diagnosis of trichinosis should be based on three main criteria: (1) clinical findings (fever; myalgias; eyelid and/or facial edema; gastrointestinal symptoms; and subconjunctival, subungual, and retinal hemorrhages); (2) laboratory findings (nonspecific eosinophilia and increased levels of muscle enzymes, antibody detection, and/or detection of larvae in a muscle biopsy); and (3) epidemiologic investigation.

**Differential Diagnosis**

The classic symptoms are pathognomonic if one is aware of this disease. It has to be distinguished from gastrointestinal pathogens, serum sickness, dermatomyositis, typhoid fever, sinotitis (facial swelling is unilateral), influenza with myopathy, toxocariasis, and invasive schistosomiasis.

**Prevention**

Because a microscopic examination must be performed, meat in the United States is not inspected for trichinosis. Although all states require the cooking of hog swill, hog-to-hog or hog-to-rat cycles may continue. All pork and sylvatic meat (eg, bear or walrus) should be cooked at least >160°F. Freezing meat to at least 5°F for 3 weeks may also prevent transmission. Animals used for food should not be fed or allowed access to raw meat.

**Treatment**

Albendazole (400 mg twice daily for 8–14 days) is the drug of choice for treatment of trichinosis. Mebendazole is an acceptable alternative and can be given at a dose of 200–400 mg three times a day for 3 days followed by 400–500 mg three times a day for 10 days. Concurrent corticosteroids (prednisone 30–60 mg/d for 10–15 days) are used for treatment of severe symptoms. Administration of analgesics is sometimes required.

**Prognosis**

Prognosis for severe cases with cardiac and cerebral complications is poor, with a mortality rate around 5%. In milder cases, prognosis is good, and most patients’ symptoms disappear within 2–6 months.

http://www.cdc.gov/parasites/trichinellosis/.

8. Raccoon Roundworm Infections

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Eosinophilic meningoencephalitis or encephalopathy.
- Ocular larva migrans.
- Contact with raccoons or raccoon feces.

**General Considerations**

Human infections with *Baylisascaris procyonis*, the raccoon roundworm, are increasingly recognized, particularly in children. The definitive host of this ascarid is the raccoon. Humans who ingest the eggs excreted in raccoon feces become intermediate hosts when the larvae penetrate the gut and disseminate via the bloodstream to the brain, eyes, viscera, and muscles. Young age, pica, and exposure to raccoon feces represent the main risk factors for this infection. Most of the infections are asymptomatic, but cases of severe encephalitis (neural larva migrans) and endophthalmitis (ocular larva migrans) occur. Symptoms typically begin 2–4 weeks after inoculation. CNS infections characteristically present as acute, rapidly progressive encephalitis with eosinophilic pleocytosis of the CSF (varies from 4% to 68% eosinophils in mild pleocytosis). Both CNS and ocular infections resemble other larva migrans infections such as toxocariasis; therefore *B procyonis* should be considered in the differential diagnosis of these infections when *Toxocara* serology is negative. The diagnosis of *B procyonis* is established by observing the larvae on examination of tissue biopsies or by serology (of serum or CSF), and should be considered in the differential diagnosis in anyone with CSF eosinophilia. Antihelmintic drugs have not been shown to have any beneficial effect for the treatment of baylisascariasis, since they lack larvicidal effects in human tissues. Nevertheless, albendazole (20–40 mg/kg/d for 1–4 weeks) has been used to treat most cases, together with anti-inflammatory drugs. Complete resolution of symptoms has not been achieved thus far. Immediate prophylactic treatment with albendazole (25 mg/kg daily for 20 days) should be considered for those with known ingestion of raccoon feces.

http://www.cdc.gov/parasites/baylisascaris/.

---

**CESTODE INFECTIONS (FLUKES)**

1. Taeniasis & Cysticercosis

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Mild abdominal pain; passage of worm segments (taeniasis).
- Focal seizures, headaches (neurocysticercosis).
- Cysticerci present in biopsy specimens, on plain films (as calcified masses), or on CT scan or magnetic resonance imaging (MRI).
- Proglottids and eggs in feces; specific antibodies in serum or CSF.

**General Considerations**

Pigs are the usual intermediate host of the tapeworm *Taenia solium*. Human cysticercosis occurs when the eggs, which are excreted in the feces of a person infected with the parasite, are ingested. Importantly, cysticercosis cannot be acquired by eating pork. Ingestion of infected pork results in adult tapeworm infection (taeniasis) because infected pork contains the larval cysts that develop into the adult tapeworm but does not contain the eggs which cause cysticercosis.

Larvae released from ingested eggs enter the circulation to encyst in a variety of tissues, especially muscle and brain. Full larval maturation occurs in 2 months, but the cysts cause little inflammation until the larvae die months to years later. Inflammatory edema ensues with calcification or disappearance of the cyst. A slowly expanding mass of sterile cysts at the base of the brain may cause obstructive hydrocephalus (racemose cysticercosis).

*T solium* and the beef tapeworm (*Taenia saginata*), which can cause taeniasis but not cysticercosis, are distributed worldwide. Contamination of foods by eggs in human feces allows person-to-person spread without exposure to meat or travel to endemic areas. Asymptomatic cases are common, but *T solium* is the most common helminth infection of the CNS and a leading cause of acquired epilepsy in the world.

**Clinical Findings**

A. Symptoms and Signs

1. Taeniasis—In most tapeworm infections, the only clinical manifestation is the passage of fecal proglottids, which are white, motile segments of tapeworm 1–2 cm in size. They occasionally crawl out onto the skin and down the leg,
especially the larger *T. saginata*. Children may harbor the adult worm for years and complain of abdominal pain, anorexia, and diarrhea.

2. Cysticercosis—In the parenchymatous form, the parasite lodges in the brain as a single or multiple cysts. Pericystic inflammation results in granuloma formation, which is the cause of seizures in most patients. The initial stage of the cyst is viable, where the scolex exists within the cyst and there is minimal or no enhancement due to a limited host immune response. As the scolex dies, either due to the host immune response or cysticidal treatment there is a strong immune response, characterized by strong enhancement on CT or MRI. As the cyst further degenerates, it calcifies, which is recognized as punctuate calcification on CT scan. Brain cysts may remain silent or cause seizures, headache, hydrocephalus, and basilar meningitis. Rarely, the spinal cord is involved. Neurocysticercosis manifests an average of 5 years after exposure, but may cause symptoms in the first year of life. In the eyes, cysts cause bleeding, retinal detachment, and uveitis. Definitive diagnosis requires histologic demonstration of larval or cyst membrane. Presumptive diagnosis is often made by the characteristics of the cysts seen on CT scan or MRI. The presence of *T. solium* eggs in feces, which is uncommon with cysticercosis (see above), supports the diagnosis.

B. Laboratory Findings

Neuroimaging is the mainstay of diagnosis of neurocysticercosis. The diagnosis should be suspected in any patient who has lived in an endemic area and presents with a compatible clinical picture and suggestive lesions on CT scans.

Eggs or proglottids may be found in feces or on the perianal skin (using the tape method employed for pinworms). Eggs of both *Taenia* species are identical. The species are identified by examination of proglottids.

Peripheral eosinophilia is minimal or absent. CSF eosinophilia is seen in 10%–75% of cases of neurocysticercosis; its presence supports an otherwise presumptive diagnosis.

ELISA antibody titers are eventually positive in up to 98% of serum specimens and over 75% of CSF specimens from patients with neurocysticercosis. Solitary cysts are associated with seropositivity less often than are multiple cysts. High titers tend to correlate with more severe disease. CSF titers are higher if cysts are near the meninges.

The differential diagnosis of neurocysticercosis includes tuberculoc granuloma, microabscesses, focal meningoencephalitis, arachnoid cyst, neoplasms, and vascular lesions.

### Treatment

**A. Taeniasis**

Praziquantel (5–10 mg/kg once) and albendazole are equally effective. Feces free of segments or ova for 3 months suggest cure.

**B. Cysticercosis**

The treatment modalities for neurocysticercosis include cysticidal agents (to kill larvae), corticosteroids (to decrease or prevent the inflammatory reaction), antiepileptic drugs (if seizures are present), and surgery (to remove cysts or for placement of a shunt for hydrocephalus). Most experts would recommend treatment with a cysticidal agent in most cases of neurocysticercosis, except in patients with inactive, calcified lesions. In patients with viable parenchymal cysts, cysticidal therapy decreases the burden of parasites and the number of seizures. Similarly, cysticidal therapy is associated with more complete and faster resolution on imaging and fewer seizures in patients with a single, small enhancing lesion. Ophthalmic examination should be conducted prior to cysticidal therapy to rule out intraocular cysts.

Albendazole, 15 mg/kg/d (maximum, 800 mg) divided in two doses daily for 8–15 days, is the treatment of choice. Larval death may result in clinical worsening because of inflammatory edema. A concurrent course of dexamethasone (0.1 mg/kg/day to a max of 6 mg/day) is recommended to decrease these symptoms. Corticosteroids are mandatory treatment for large intraventricular cysts and encephalitis (dexamethasone 0.1 mg/kg/day or prednisolone 1 mg/kg/day for as long as needed). Giant subarachnoidal cysts may require more than one cycle of therapy or surgery (or both). Minimally invasive neurosurgery (neuroendoscopic extraction) is the currently recommended management of intraventricular cysts. Follow-up scans every several months help assess the response to therapy.

#### Prevention

Prevention requires proper cooking of meat, careful washing of raw vegetables and fruits, treating intestinal carriers, avoiding the use of human excrement for fertilizer, and providing proper sanitary facilities.

#### Prognosis

The prognosis is good in intestinal taeniasis. Symptoms associated with a few cerebral cysts may disappear in a few months; heavy brain infections may cause death or chronic neurologic impairment. Seizures may persist even in those patients with only calcified lesions and anticonvulsants may be needed indefinitely.

http://www.cdc.gov/parasites/cysticercosis/.

2. Hymenolepiasis

_Hymenolepis nana_, the cosmopolitan human tapeworm, is a common parasite of children; _Hymenolepis diminuta_, the rat tapeworm, is rare. The former is capable of causing autoinfection. Larvae hatched from ingested eggs penetrate the intestinal wall and then reenter the lumen to mature into adults. Their eggs are immediately infectious for the same or a new host. The adult is only a few centimeters long. Finding the characteristic eggs in feces is diagnostic.

_H diminuta_ has an intermediate stage in rat fleas and other insects; children are infected when they ingest these insects.

Light infections with either tapeworm are usually asymptomatic; heavy infection can cause diarrhea and abdominal pain. Therapy is with praziquantel (25 mg/kg once).

http://www.cdc.gov/parasites/hymenolepis/.

3. Echinococcosis

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Cystic tumors of liver, lungs, kidneys, bones, brain, and other organs.
- Eosinophilia.
- Urticaria and pruritus if cysts rupture.
- Protoscoleces or daughter cysts in the primary cyst.
- Positive serology.
- Epidemiologic evidence of exposure.

**Clinical Findings**

### A. Symptoms and Signs

The clinical manifestations of echinococcosis are variable and depend primarily on the site, size, and condition of the cysts. The rates of growth of cysts are variable, and range between 1 and 5 cm in diameter per year. A slowly growing cyst often goes unnoticed until it causes dysfunction due to its size. Liver cysts can cause hepatomegaly, right upper quadrant pain, nausea, and vomiting. If a cyst ruptures, the sudden release of its contents can result in a severe allergic reaction. Cysts may cause biliary obstruction. Most hepatic cysts are in the right lobe.

Rupture of a pulmonary cyst causes coughing, dyspnea, wheezing, urticaria, chest pain, and hemoptysis; cyst and worm remnants are found in sputum. Brain cysts may cause focal neurologic signs and convulsions; renal cysts cause pain and hematuria; bone cysts cause pain.

**B. Laboratory Findings**

Antibody assays are useful to confirm a presumptive diagnosis, but some patients with echinococcosis do not have a detectable immune response (related to the integrity of the cyst and sequestration of echinococcal antigens inside the cyst). ELISA is the method most widely used for antibody testing.

Confirmation may be obtained by ultrasonography-guided fine-needle aspiration coupled with parasitologic examination for protoscoleces, rostellar hooks, antigens, or DNA. Eosinophilia is present in only about 25% of patients. Serologic tests are useful for diagnosis and follow-up of therapy.

**C. Imaging**

The presence of a cyst-like mass in a person with appropriate epidemiologic exposure supports the diagnosis. Visualization of daughter cysts is highly suggestive of echinococcosis. CT, MRI, and ultrasonography are useful for the diagnosis of deep-seated lesions. Abdominal ultrasonography is the most widely used diagnostic tool. Pulmonary or bone cysts may be visible on plain films.

**Differential Diagnosis**

Tumors, bacterial or amebic abscess, cavitary tuberculosis (pulmonary), mycoses, and benign cysts must be considered.

**Complications**

Sudden cyst rupture with anaphylaxis and death is the worst complication. If the patient survives, secondary infections
from seeding of daughter cysts may occur. Segmental lung collapse, secondary bacterial infections, effects of increased intracranial pressure, and severe renal damage due to renal cysts are other potential complications.

**Treatment**

There is no “best” treatment option for cystic echinococcus and no clinical trial has compared all the different treatment modalities. Treatment indications are complex and based on cyst characteristics, available medical/surgical expertise and equipment, and adherence of patients to long-term monitoring. Because treatment involves a variety of options and expertise, patients should be referred to recognized reference and national/regional treatment centers, whenever available. Definitive therapy of *E* multilocularis requires meticulous surgical removal of the cysts. A surgeon familiar with this disease should be consulted. Albendazole chemotherapy should be initiated for several days prior to surgery. Chemotherapy alone has been shown to cure about one-third of patients. Albendazole (15 mg/kg/d divided in 2 doses for 3 months, max 400 mg twice daily), sometimes with the addition of praziquantel, is the regimen of choice. A third treatment option is a four-step procedure (PAIR; puncture, aspiration, injection, and reaspiration). This procedure consists of (1) percutaneous puncture using ultrasound guidance, (2) aspiration of liquid contents, (3) injection of a protoscolicidal agent (95% ethanol or hypertonic saline for at least 15 minutes), and (4) reaspiration. PAIR is indicated for uncomplicated cases. If the cyst leaks or ruptures, the allergic symptoms must be managed immediately. For alveolar echinococcus, radical surgery for complete resection of the cyst is the goal. In some patients (particularly in those in whom complete resection is not possible), lifetime chemotherapy may be required.

**Prognosis**

Patients with large liver cysts may be asymptomatic for years. Surgery is often curative for lung and liver cysts, but not always for cysts in other locations.

**Schistosomiasis**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Transient pruritic rash after exposure to freshwater.
- Fever, urticaria, arthralgias, cough, lymphadenitis, and eosinophilia.
- Weight loss, anorexia, hepatosplenomegaly, or hematuria.
- Eggs in stool, urine, or rectal biopsy specimens.

**General Considerations**

One of the most common serious parasitic diseases, schistosomiasis, is caused by several species of *Schistosoma* flukes. *Schistosoma japonicum*, *Schistosoma mekongi*, and *S mansoni* involve the intestines and *Schistosoma haematobium*, the urinary tract. The first two species are found in eastern and southeastern Asia; *S mansoni* in tropical Africa, the Caribbean, and parts of South America; and *S haematobium* in Africa. Important transmission sites include Lake Malawi and Lake Victoria in Africa, Poyang and Dongting Lakes in China, and along the Mekong River in Laos.

Infection is caused by free-swimming larvae (cercariae), which emerge from the intermediate hosts, certain species of freshwater snails. The cercariae penetrate human skin, migrate to the liver, and mature into adults, which then migrate through the portal vein to lodge in the bladder veins (*S haematobium*), superior mesenteric veins (*S mekongi* and *S japonicum*), or inferior mesenteric veins (*S mansoni*). Clinical disease results primarily from inflammation caused by the many eggs that are laid in the perivascular tissues or that embolize to the liver. Escape of ova into bowel or bladder lumen allows microscopic visualization and diagnosis from stool or urine specimens, as well as contamination of freshwater and infection of the snail hosts that ingest them.

**Clinical Findings**

Much of the population in endemic areas is infected but asymptomatic. Only heavy infections produce symptoms.

**A. Symptoms and Signs**

Schistosomiasis progresses in three distinct phases: acute, chronic, and advanced disease. The cercarial penetration
may cause a maculopapular, pruritic rash, comprising discrete, erythematous, raised lesions that vary in size from 1 to 3 cm. The symptoms of acute schistosomiasis (Katayama syndrome) can last from days to weeks, and can include fever, malaise, cough, diarrhea, hematuria, and right upper quadrant pain. The chronic stages of disease are characterized by hepatic fibrosis, portal hypertension, splenomegaly, ascites, and bleeding from esophageal varices. The chronic inflammation in the urinary tract associated with \( S. h. \) infections may result in obstructive uropathy, stones, infection, bladder cancer, fistulas, and anemia due to chronic hematuria. Terminal hematuria in children from an endemic region is a red flag for urinary schistosomiasis. Spinal cord granulomas and paraplegia due to egg embolization into the Batson plexus have been reported.

B. Laboratory Findings

The diagnosis is made by finding the species-specific eggs in feces (\( S. j. \), \( S. m. \), \( S. m. \), and occasionally \( S. h. \)) or urine (\( S. h. \) and occasionally \( S. m. \)). If no eggs are found, concentration methods should be used. Because the shedding of eggs can vary, three specimens should be obtained. Urine specimens should be collected between 10 AM and 2 PM to coincide with the timing of maximal egg secretion. Testing should wait until 2 months after the last known freshwater contact as this is the time required for worms to start producing eggs following infection. A rectal biopsy may reveal \( S. m. \) and should be done if other specimens are negative. Serological tests are also available and may be helpful in making the diagnosis in patients who are not excreting eggs. Peripheral eosinophilia is common, and eosinophils may be seen in urine.

Prevention

The best prevention is to avoid contact with contaminated freshwater in endemic areas. Efforts to destroy the snail hosts have been successful in areas of accelerated economic development.

Treatment

A. Specific Measures

Praziquantel is the treatment of choice for schistosomiasis. A dosage of 40 mg/kg/d in two divided doses (\( S. m. \) or \( S. h. \)) over 1 day or 20 mg/kg three times a day (\( S. j. \) or \( S. m. \)) over 1 day is very effective and nontoxic. Praziquantel has no effect on eggs and immature worms and therefore a repeat dose 4–6 weeks later is sometimes needed.

B. General Measures

Therapy of nutritional deficiency or secondary bacterial infections may be needed. The patient’s urinary tract should be evaluated carefully in \( S. h. \) infection; reconstructive surgery may be needed. Hepatic fibrosis requires careful evaluation of the portal venous system and surgical management of portal hypertension when appropriate.

Prognosis

Therapy decreases the worm burden and liver size, despite continued exposure in endemic areas. Early disease responds well to therapy, but once significant scarring or severe inflammation has occurred, eradication of the parasites is of little benefit.

Mycotic Infections

Fungi can be classified as yeasts, which are unicellular and reproduce by budding; as molds, which are multicellular and consist of tubular structures (hyphae) and grow by elongation and branching; or as dimorphic fungi, which can exist either as yeasts or molds depending on environmental conditions. Categorization according to anatomic and epidemiologic features is shown in Table 43–6. Fungal cells are taxonomically distinct from plant and animal cells. These differences, especially cell wall and cell membrane components, are utilized for diagnosis and are the basis of specific therapy.

In the United States, systemic disease in normal hosts is commonly caused by three organisms—\( Coccidioides \), \( Histoplasma \), and \( Blastomyces \)—which are restricted to certain geographic areas. Prior residence in or travel to these areas, even for a brief time, is a prerequisite for inclusion in a differential diagnosis. Of these three, \( Histoplasma \) most often relapses years later in patients who are immunosuppressed.

Immunosuppression (especially depressed T-cell–mediated immunity), foreign bodies (eg, urinary and central catheters), ulceration of gastrointestinal and respiratory mucosa, severe burns, broad-spectrum antimicrobial therapy, malnutrition, HIV infection, and neutropenia or neutrophil defects are major risk factors for opportunistic fungal disease.

Laboratory diagnosis may be difficult because of the small number of fungi present in some lesions, slow growth of some organisms, and difficulty in distinguishing...

<sup>a</sup>Candida and Sporothrix in immunocompromised patients may cause severe, rapidly progressive disease and require systemic therapy.

<sup>b</sup>Sporotrichosis may require biopsy for diagnosis.

<sup>c</sup>Can be self-limited in normal host.

<sup>d</sup>Asymptomatically infects many normal hosts.

<sup>e</sup>Except Cryptococcus, which is often diagnosed by antigen detection.

KOH, potassium hydroxide.

Normal colonization of mucosal surfaces, by some fungi, from infection. A tissue biopsy with fungal stains and culture is the best method for diagnosing systemic disease with some fungi. Repeat blood cultures may be negative even in the presence of intravascular infections. Serologic tests are useful for diagnosing coccidioidomycosis and histoplasmosis, and antigen detection in urine and blood is useful for diagnosing blastomycosis, histoplasmosis, cryptococcosis, and aspergillosis.

The common superficial fungal infections of the hair and skin are discussed in Chapter 15.

Blastomycosis

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Residence in, or travel to, an endemic area.
- In immunocompetent patients, most often a self-limited flu-like illness; acute pneumonia occurs in a minority of cases.
- Complications include progressive pneumonia and disseminated disease (CNS, skin, bone and joints, genitourinary tract).
- Diagnosis by culture of specimens from bronchoscopy, skin, or other tissue.

**General Considerations**

The causative fungus, *Blastomyces dermatitidis*, is found in soil primarily in the Mississippi and Ohio River valleys, additional southeastern and south central states, and the states bordering the Great Lakes. Transmission is by inhalation of
spores. Subclinical disease is common. Severe disease is much more common in adults and males. In children, infection rates are similar in both sexes.

**Clinical Findings**

**A. Symptoms and Signs**

Primary infection is often unrecognized or produces pneumonia. Acute symptoms include cough with purulent sputum, chest pain, headache, weight loss, night sweats, and fever. These occur several weeks to months after inoculation. Acute infection is often seen in conjunction with heavy point source exposure (such as around excavations). Infection is most often self-limited in immunocompetent patients, but in some patients an indolent progressive pulmonary disease occurs after an incubation period of 20–100 (median 45) days. Cutaneous lesions usually represent disseminated disease; local primary inoculation is rare. Skin lesions are slowly progressive and ulcerative with a sharp, heaped-up border or verrucous appearance. Bone disease resembles other forms of chronic osteomyelitis. Lytic skull lesions in children are typical, but long bones, vertebrae, and the pelvis may be involved. Extrapulmonary disease occurs in 25%–40% of patients with progressive disease. A total body radiographic examination is advisable when blastomycosis is diagnosed in the skin or another nonpulmonary site. Lymph nodes and brain may be involved, but the genitourinary tract involvement characteristic of dissemination in adults is rare in prepubertal children.

**B. Laboratory Findings**

An initial suppurative response is followed by an increase in the number of mononuclear cells, and subsequent formation of noncaseating granulomas. Diagnosis requires isolation or visualization of the fungus. Pulmonary specimens (sputum, tracheal aspirates, or lung biopsy) may be positive using conventional stains or fungal cell wall stains. The budding yeasts are thick-walled, have refractile walls, and are very large and distinctive (figure-of-eight appearance). The fungus can be grown readily in most laboratories, but a week is often required. Sputum specimens are positive in more than 80% of cases and in almost all bronchial washings, and skin lesions are positive in 80%–100%. Antibody tests are generally not helpful for diagnosis, but an ELISA antigen detection method, similar to that used for histoplasmosis, readily detects Blastomyces antigen in serum, urine, and lung lavage fluids. In this assay, there is cross-reactivity with histoplasmosis and tuberculosis. Miliary patterns also occur with acute infection. Chronic disease can develop in the upper lobes, with cavities and fibronodular infiltrations similar to those seen in tuberculosis. However, unlike tuberculosis or histoplasmosis, these lesions rarely caseate or calcify.

**Differential Diagnosis**

Primary pulmonary infection resembles acute viral, bacterial, or mycoplasmal infections, and is generally confused with atypical community-acquired pneumonia. Blastomycosis should be considered when a significant pulmonary infection in an endemic area fails to respond to antibiotic therapy. Subacute infection mimics tuberculosis, histoplasmosis, and coccidioidomycosis. Chronic pulmonary or disseminated disease must be differentiated from cancer, tuberculosis, or other fungal infections.

**Treatment**

If the patient is symptomatic at the time of diagnosis, and has moderately severe or life-threatening blastomycosis (especially if immunocompromised patient), or has CNS infections, therapy should be initiated with the lipid formulation of amphotericin B (3–5 mg/kg intravenously) for 1–2 weeks or until improved. This is followed by oral itraconazole (5–10 mg/kg/d; divided into two doses) for 6 months. Itraconazole drug levels are valuable for monitoring therapy in severely ill patients. Mild to moderate blastomycosis is often treated with oral itraconazole alone for 6–12 months. Bone disease may require a full year of itraconazole therapy. Surgical debridement is required for devitalized bone, drainage of large abscesses, and pulmonary lesions not responding to medical therapy.

---

**Candidiasis**

In normal or immunosuppressed individuals: superficial infections (oral thrush or ulcerations, vulvovaginitis, erythematous intertriginous rash with satellite lesions); fungemia related to intravascular devices.
In immunosuppressed individuals: systemic infections (candidemia with renal, hepatic, splenic, pulmonary, or cerebral abscesses); chorioretinitis; cutaneous nodules.

In either patient population: budding yeast and pseudohyphae are seen in biopsy specimens, body fluids, or scrapings of lesions; positive culture.

General Considerations

Disease due to Candida is caused by Candida albicans in 60%-80% of cases; severe systemic infection may also be caused by Candida tropicalis, Candida parapsilosis, Candida glabrata, and a few other Candida species. Speciation is important because of differences in pathogenicity and response to antifungal therapy. In tissue, pseudohyphae or budding yeast (or both) are seen. Candida grows on routine media more slowly than many bacteria; growth is usually evident on agar after 2-3 days and in blood culture in 2-7 days.

Candida albicans is ubiquitous, usually in small numbers, on skin, mucous membranes, or in the intestinal tract. Normal bacterial flora, intact epithelial barriers, neutrophils, and macrophages in conjunction with antibody and complement and normal lymphocyte function are factors in preventing invasion. Disseminated infection is almost always preceded by prolonged broad-spectrum antibiotic therapy, instrumentation (including intravascular catheters), and/or immunosuppression. Patients with diabetes mellitus are especially prone to superficial Candida infection; thrush and vaginitis are most common. Candida is the fourth most common blood isolate in hospitals in the United States and is a common cause of catheter-related urinary tract infection.

Clinical Findings

A. Symptoms and Signs

1. Oral candidiasis (thrush)—Adherent creamy white plaques on the buccal, gingival, or lingual mucosa are seen. These may be painful. Lesions may be few and asymptomatic, or they may be extensive, extending into the esophagus. Thrush is very common in otherwise normal infants in the first weeks of life; it may last weeks despite topical therapy. Spontaneous thrush in older children is unusual unless they have recently received antimicrobials. Corticosteroid inhalation for asthma predisposes patients to thrush. HIV infection should be considered if there is no other reason for oral thrush, or if it is persistent or recurrent. Angular cheilitis is the name given to painful erythematous fissures caused by Candida at the corners of the mouth, often in association with a vitamin or iron deficiency.

2. Vaginal infection—Vulvovaginitis occurs in sexually active girls, in diabetic patients, and in girls receiving antibiotics. Thick, odorless, cheesy discharge with intense pruritus is typical. The vagina and labia are usually erythematous and swollen. Outbreaks are more frequent before menses.

3. Skin infection

A. Dermatitis—Diaper dermatitis is often due entirely or partly to Candida. Pronounced erythema with a sharply defined margin and satellite lesions is typical. Pustules, vesicles, papules, or scales may be seen. Weeping, eroded lesions with a scalloped border are common. Any moist area, such as axillae, under breasts, and inguinal or neck folds, may be involved.

B. Congenital skin lesions—These lesions may be seen in infants born to women with Candida amniotic. A red maculopapular or pustular rash is seen. Dissemination may occur in premature infants or in term infants after prolonged rupture of membranes.

C. Scattered red papules or nodules—Such findings in immunocompromised patients may represent cutaneous dissemination.

D. Paronychia and onychomycosis—These conditions occur in immunocompetent children, but are often associated with immunosuppression, hypoparathyroidism, or adrenal insufficiency (Candida endocrinopathy syndrome). The selective absence of specific innate and T-cell responses to Candida can lead to marked, chronic skin and nail infections called chronic mucocutaneous candidiasis.

E. Chronic draining otitis media—This problem may occur in patients who have received multiple courses of antibiotics and are superinfected with Candida.

4. Enteric infection—Esophageal involvement in immunocompromised patients is the most common enteric manifestation, resulting in substernal pain, dysphagia, painful swallowing, and anorexia. Nausea and vomiting are common in young children. Most patients do not have thrush. Stomach or intestinal ulcers also occur.

5. Pulmonary infection—Because the organism frequently colonizes the upper respiratory tract, it is commonly isolated from respiratory secretions. Thus, demonstration of tissue invasion is needed to diagnose Candida pneumonia or tracheitis. It is rare, seen mainly in immunosuppressed patients and patients intubated for long periods, usually while taking antibiotics. The infection may cause fever, cough, abscesses, nodular infiltrates, and effusion.

6. Renal infection—Candiduria may be the only manifestation of disseminated disease. More often, candiduria is associated with instrumentation, an indwelling catheter, or anatomic abnormality of the urinary tract. Symptoms
of cystitis may be present. Masses of *Candida* may obstruct ureters and cause obstructive nephropathy. *Candida* casts in the urine suggest renal tissue infection.

7. *Other infections*—Myocarditis, meningitis, and osteomyelitis usually occur only in immunocompromised patients or neonates, generally in those with high-grade candidemia. Endocarditis may occur on an artificial or abnormal heart valve, especially when an intravascular line is present.

8. *Disseminated candidiasis*—Skin and mucosal colonization precedes, but does not predict dissemination. Too often, dissemination is confused with bacterial sepsis. This occurs in neonates—especially premature infants—in an intensive care unit setting, and is recognized when the infant fails to respond to antibiotics or when candidemia is documented. Invasive disease can occur in >50% of very low-birth-weight infants. These infants often have unexplained feeding intolerance, cardiovascular instability, apnea, or new or worsening respiratory failure, glucose intolerance, thrombocytopenia, or hyperbilirubinemia. A careful search in immunocompromised patients should be carried out for lesions suggestive of disseminated *Candida* (retinal cotton-wool spots or chorioretinitis; nodular dermal abscesses). If these findings are absent, diagnosis is often based presumptively on the presence of a compatible illness in an immunocompromised patient; a burn patient; or a patient with prolonged postsurgical or intensive care unit course who has no other cause for the symptoms; and who fails to respond to antimicrobials. Such patients usually have *Candida* colonization of mucosal surfaces. Treatment for presumptive infection is often undertaken because candidemia is not identified antemortem in many such patients.

Hepatosplenic and renal candidiasis occurs in immunosuppressed patients. The typical case consists of a severely neutropenic patient who develops chronic fever, variable abdominal pain, and abnormal liver function tests. No causative bacterial pathogen is isolated, and there is no response to antimicrobials. Symptoms persist even when neutrophils return. Ultrasound or CT scan of the liver, spleen, and kidney demonstrates multiple round lesions. Biopsy is needed to confirm the diagnosis.

B. *Laboratory Findings*

Budding yeast cells are easily seen in scrapings or other samples. A wet mount preparation of vaginal secretions is 40%–50% sensitive; this is increased to 50%–70% with the addition of 10% potassium hydroxide to the sample. The use of a Gram-stained smear is 70%–100% sensitive. The presence of pseudohyphae suggests tissue invasion. Positive cultures from nonsterile sites may reflect colonization and need to be carefully evaluated, but *Candida* should never be considered a contaminant in cultures from normally sterile sites. Ninety-five percent of positive blood cultures will be detected within 3 days, but cultures may remain negative (10%–40%) even with disseminated disease or endocarditis. *Candida* in any number in appropriately collected urine suggests true infection. Antigen tests are not sensitive or specific enough for clinical use. The ability of yeast to form germ tubes when incubated in human serum gives a presumptive speciation for *C. albicans*.

Differential Diagnosis

Thrush may resemble formula (which can be easily wiped away with a tongue blade or swab, revealing normal mucosa without underlying erythema or erosion), other types of ulcers (including herpes), burns, or oral changes induced by chemotherapy. Skin lesions may resemble contact, allergic, chemical, or bacterial dermatitis; miliaria; folliculitis; or eczema. Vulvovaginitis needs to be distinguished from other causes of vaginal discharge and discomfort. Candidemia and systemic infection should be considered in any seriously ill patient with the risk factors previously mentioned.

Complications

Failure to recognize disseminated disease early is the greatest complication. Arthritis and meningitis occur more often in neonates than in older children. Blindness from retinitis, massive emboli from large vegetations of endocarditis, and abscesses in any organ are other complications. The greater the length or extent of immunosuppression, and the longer the delay before therapy, the more likely that complications will occur.

Treatment

A. Oral Candidiasis

In infants, oral nystatin suspension (100,000 units four to six times a day in the buccal fold after feeding until resolution) usually suffices. Nystatin must come in contact with the lesions because it is not absorbed systemically. Older children may use it as a mouthwash (200,000–500,000 units five times a day), although it is poorly tolerated because of its taste. Clotrimazole troches (10 mg) four times a day are an alternative in older children. Prolonged therapy with either agent or more frequent dosing may be needed. Painting the lesions with a cotton swab dipped in gentian violet (0.5%–1%) is visually dramatic and messy, but may help refractory cases. Eradication of *Candida* from pacifiers, bottle nipples, toys, or the mother’s breasts (if the infant is breast-feeding and there is candidal infection of the nipples) may be helpful.

Oral azoles, such as fluconazole (6 mg/kg/d), are effective in older children with candidal infection refractory to nystatin. Discontinuation of antibiotics or corticosteroids is advised when possible.
B. Skin Infection

Cutaneous infection usually responds to a cream or lotion containing nystatin, amphotericin B, or an imidazole (miconazole, clotrimazole, and others). Associated inflammation such as severe diaper dermatitis is helped by concurrent use of a topical mild corticosteroid cream, such as 1% hydrocortisone. One approach is to keep the involved area dry; a heat lamp and nystatin powder may be used. Suppression of intestinal Candida with nystatin and eradicating thrush may speed recovery and prevent recurrence of the diaper dermatitis.

C. Vaginal Infections

Vulvovaginal candidiasis (see Chapter 44) is treated with clotrimazole, miconazole, triazoles, or nystatin (cheapest if generic is used) suppositories or creams, usually applied once nightly for 3–7 days. A high-dose topical clotrimazole formulation need be given for only a single night. Oral azole therapy is equally effective. A single 150-mg oral dose of fluconazole is effective for vaginitis. It is more expensive but very convenient. Candida balanitis in sexual partners should be treated, but no controlled study has shown that treating colonization of male sexual partners prevents recurrence in females. Frequent recurrent infections may require elimination of risk factors, the use of oral therapy, or some prophylactic antifungal therapy, such as a single dose of fluconazole weekly for 6 months.

D. Renal Infection

Candiduria in an immunocompetent host with a urinary catheter may respond to its removal. Candiduria is treated in all high-risk patients, usually with a 7- to 14-day course of fluconazole (3–6 mg/kg/d), which is concentrated in the urine. Amphotericin B may be required in patients with fluconazole-resistant organisms. Renal abscesses or ureteral fungus balls require intravenous antifungal therapy, and surgical debridement may be required. Removal of an indwelling catheter is imperative.

E. Systemic Infection

1. Disseminated Candida infection—Systemic infection is dangerous and resistant to therapy. Surgical drainage of abscesses and removal of all infected tissue (eg, a heart valve) are required for cure. Hepatosplenic candidiasis should be treated until all lesions have disappeared or are calcified on imaging studies. Treatment of systemic infection has traditionally utilized amphotericin B, but lipid forms of amphotericin B retain the antifungal potency of the free drug and are much better tolerated. Although they are much more expensive than amphotericin B, they are indicated for patients who are intolerant of conventional therapy and for those whose infection is refractory to treatment or who have a high likelihood of developing renal toxicity from such therapy.

Flucytosine (50–75 mg/kg/d orally in four doses; keep serum levels < 75 mcg/mL) may be additive or synergistic to amphotericin B. Unlike amphotericin B, flucytosine penetrates tissues well. It should not be used as a single agent in serious infections because resistance develops rapidly.

Fluconazole and itraconazole (best absorbed from the liquid solution) and newer azole drugs, such as voriconazole and posaconazole, and a new class of drugs, echinocandins, are used interchangeably or in conjunction with amphotericin. They are often preferred because in general they are less toxic. They are acceptable alternatives for serious Candida infections in nonneutropenic patients and are often effective as first-line therapy in immunocompromised patients. Fluconazole is well absorbed (oral and intravenous therapy are equivalent), reasonably nontoxic, and effective for a variety of Candida infections.

Fluconazole dosage is 8–12 mg/kg/d in a single daily dose for initial therapy of severely ill children. Selected patients with prolonged immunosuppression (eg, after bone marrow transplantation) should receive prophylactic azole, echinocandin, or intermittent amphotericin B prophylaxis. The decision to use systemic azole therapy should include consideration of the local experience with azole-resistant Candida and if the patient had recent prophylaxis or treatment with azoles. Susceptibility testing for Candida species is now available to guide this decision. Candida glabrata and C krusei are common isolates that may be resistant to fluconazole; these are often susceptible to the newer azoles and echinocandins. Candida lusitaniae is usually resistant to amphotericin.

Correction of predisposing factors is important (eg, discontinuing antibiotics and immunosuppressives, improving control of diabetes, and removing infected devices and lines).

2. Candidemia—Infected central venous lines must be removed immediately; this alone often is curative. If the infection is considered limited to the line and environs, a 14-day course (after the last positive culture) of a systemic antifungal agent following line removal is recommended for nonneutropenic patients. This is because of the late occurrence of focal Candida infection, especially retinal infection, in some cases. Persistent fever and candidemia suggest infected thrombus, endocarditis, or tissue infection.

Prognosis

Superficial disease in normal hosts has a good prognosis; in abnormal hosts, it may be refractory to therapy. Early therapy of systemic disease is often curative if the underlying
immune response is adequate. The outcome is poor when therapy is delayed or when host response is inadequate.

Coccidioidomycosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Residence in, or travel to, an endemic area.
- Primary pulmonary form: fever, chest pain, cough, anorexia, weight loss, and often a macular rash, erythema nodosum, or erythema multiforme.
- Primary cutaneous form: skin trauma followed in 1–3 weeks by an ulcer and regional adenopathy.
- Spherules seen in pus, sputum, CSF, joint fluid; positive culture.
- Appearance of precipitating (early) and complement-fixing antibodies (late).

General Considerations

Coccidioidomycosis is caused by the dimorphic fungus Coccidioides (immitis or posadasii), which are endemic in the Sonoran Desert areas of western Texas, southern New Mexico and Arizona, southern California, northern Mexico, and South America. Infection results from inhalation or inoculation of arthrospores (highly contagious and readily airborne in the dry climate). Even brief travel in or through an endemic area, especially during windy seasons, may result in infection. Human-to-human transmission does not occur. More than half of all infections are asymptomatic, and less than 5% are associated with significant pulmonary disease. Chronic pulmonary disease or dissemination occurs in less than 1% of cases.

Clinical Findings

A. Symptoms and Signs

1. Primary disease—The incubation period is 10–16 days (range, 7–28 days). Symptoms vary from those of a mild fever and arthralgia to severe influenza-like illness with high fever, nonproductive cough, pleurisy, myalgias, arthralgias, headache, and night sweats. Upper respiratory tract signs are uncommon. Severe pleuritic chest pain suggests this diagnosis. Signs vary from none to rash, rales, pleural rubs, and signs of pulmonary consolidation. Weight loss may occur.

2. Skin disease—Up to 10% of children develop erythema nodosum or erythema multiforme. These manifestations imply a favorable host response to the organism. Less specific maculopapular eruptions occur in a larger number of children. Skin lesions can occur following fungemia. Primary skin inoculation sites develop indurated ulcers with local adenopathy. Contiguous involvement of skin from deep infection in nodes or bone also occurs. The presence of chronic skin lesions should lead to a search for other areas of infection (eg, lungs).

3. Chronic pulmonary disease—This is uncommon in children. Chronic disease is manifested by chronic cough (occasionally with hemoptysis), weight loss, pulmonary consolidation, effusion, cavitation, or pneumothorax.

4. Disseminated disease—This is less common in children than adults, and is more common in infants, neonates, pregnant women (especially during the third trimester), black people, Filipinos, American Indians, and patients with HIV or other types of immunosuppression. More than one organ may be involved. The most common extra-pulmonary sites involved are bone or joint (usually a single bone or joint; subacute or chronic swelling, pain, redness), nodes, meninges (slowly progressive meningeal signs, ataxia, vomiting, headache, and cranial neuropathies), and kidneys (dysuria and urinary frequency). As with most fungal diseases, the evolution of the illness is usually slow.

B. Laboratory Findings

Direct examination of respiratory secretions, pus, CSF, or tissue may reveal large spherules (30–60 μm) containing endospores. These are the product of coccidioidal spores germinating in tissue. The organism is detected by using periodic acid–Schiff reagent, methenamine silver, and calcofluor stains. Fluffy, gray-white colonies grow within 2–5 days on routine fungal and many other media. CSF cultures are often falsely negative.

The sedimentation rate is usually elevated. Eosinophilia may occur, particularly prior to dissemination, and is more
common in coccidioidomycosis than in many other conditions with similar symptoms. Meningitis causes a mononuclear pleocytosis (70% contain eosinophils) with elevated protein and mild hypoglycorrhachia.

Antibodies consist of precipitins (usually measurable by 2–3 weeks in 90% of cases and gone by 12 weeks) and complement-fixing antibodies (delayed for several weeks; appear as the precipitins are falling and should disappear by 8 months). Thus, serum precipitins usually indicate acute infection. The extent of the complement-fixing antibody response reflects the severity of infection. Persistent high levels suggest dissemination. Excellent ELISA assays, which detect IgM and IgG antibodies against coccidoidal antigens, become positive in some patients as early as 1–3 weeks after onset of symptoms. The presence of antibody in CSF indicates CNS infection; CSF and serum antibody titers correlate with disease progression and response to therapy.

Galactomannan antigen from *Coccidioides* is detected in urine and serum of patients. This occurs more frequently in severe disease compared to moderate disease. Testing both types of specimens should provide a diagnosis overall in more than 75% of patients.

**C. Imaging**

Approximately half of symptomatic infections are associated with abnormal chest radiographs—usually infiltrates with hilar adenopathy. Pulmonary consolidation, effusion, and thin-walled cavities may be seen. About 5% of infected patients have asymptomatic nodules or cysts after recovery. Unlike tuberculosis reactivation, apical disease is not prominent. Bone infection causes osteolysis that enhances with technetium. Cerebral imaging may show hydrocephalus and meningitis; intracranial abscesses and calcifications are unusual. Radiographic evolution of all lesions is slow.

**Differential Diagnosis**

Primary pulmonary infection resembles acute viral, bacterial, or mycoplasmal infections; subacute presentation mimics tuberculosis, histoplasmosis, and blastomycosis. Chronic pulmonary or disseminated disease must be differentiated from cancer, tuberculosis, or other fungal infections.

**Complications**

Dissemination of primary pulmonary disease is associated with permissive ethnic background, prolonged fever (> 1 month), a negative skin test, high complement-fixation antibody titer, and marked hilar adenopathy. Local pulmonary complications include effusion, empyema, and pneumothorax. Cerebral infection can cause noncommunicating hydrocephalus due to basilar meningitis.

**Treatment**

**A. Specific Measures**

Mild pulmonary infections in most normal patients require no therapy. These patients should be assessed for 1–2 years to document resolution and to identify any complications. Antifungal therapy is used for prolonged fever, weight loss (> 10%), prolonged duration of night sweats, severe pneumonitis (especially if persisting for 4–6 weeks), or any form of disseminated disease. Neonates, pregnant women, high-risk racial background, and patients with high antibody titers also receive treatment.

Lipid formulation of amphotericin B is used to treat extensive pulmonary or disseminated disease or disease in immunosuppressed patients (2–5 mg/kg/d). In general, the more rapidly progressive the infection, the more compelling the case for amphotericin B therapy. For less severe disease and for meningeval disease, fluconazole or itraconazole are preferred (duration of therapy is 3–6 months or is lifelong for meningeval disease). Measurement of serum levels is suggested to monitor therapy. Chronic fibrocavitary pneumonia is treated for at least 12 months. Itraconazole may be superior to fluconazole. Refractory meningitis may require prolonged intrathecal or intraventricular amphotericin B therapy. Pregnant patients should not receive azoles.

**B. General Measures**

Most pulmonary infections require only symptomatic therapy, self-limited activity, and good nutrition. Patients are not contagious.

**C. Surgical Measures**

Excision of chronic pulmonary cavities or abscesses may be needed. Infected nodes, sinus tracts, and bone are other operable lesions. Azole therapy should be given prior to surgery to prevent dissemination and should be continued for 4 weeks arbitrarily or until other criteria for cure are met.

**Prognosis**

Most patients recover. Even with amphotericin B, however, disseminated disease may be fatal, especially in those racially predisposed to severe disease. Reversion of the skin test to negative or a rising complement-fixing antibody titer is an ominous sign. Individuals who later in life undergo immunosuppressive therapy or develop HIV may experience reactivation of dormant disease. Thus, some transplant and oncology programs determine prior infection by serology and either provide prophylaxis or observe patients closely during periods of intense immune suppression.
Cryptococcosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Acute pneumonitis in immunocompetent individuals.
- Immunosuppressed patients especially vulnerable to CNS infection (headache, vomiting, cranial nerve palsies, meningeal signs; mononuclear cell pleocytosis).
- Cryptococcal antigen detected in CSF; also in serum and urine in some patients.
- Readily isolated on routine media.

General Considerations

_Cryptococcus neoformans_ is a ubiquitous soil yeast. It appears to survive better in soil contaminated with bird excrement, especially that of pigeons. However, most infections in humans are not associated with a history of significant contact with birds. Inhalation is the presumed route of inoculation. Infections in children are rare, even in heavily immunocompromised patients such as those with HIV infection. Immunocompetent individuals can also be infected, especially by _Cryptococcus gattii_, which is an emerging pathogen in Canada and the Pacific Northwest. Asymptomatic carriage does not occur.

Clinical Findings

A. Symptoms and Signs

1. Pulmonary disease—Pulmonary infection precedes dissemination to other organs. It is frequently asymptomatic (ie, many older children and adults have serologic evidence of prior infection) and less often clinically apparent than cryptococcal meningitis. Pneumonia is the primary manifestation in one-third of patients; CNS disease is the primary manifestation in 50% of patients. Cryptococcal pneumonia may coexist with CNS involvement. Symptoms are nonspecific and subacute—cough, weight loss, and fatigue.

2. Meningitis—The most common clinical disease is meningitis, which follows hematogenous spread from a pulmonary focus. This is much more likely to occur in an immunosuppressed patient (especially HIV). Symptoms of headache, vomiting, and fever occur over days to months. Meningeal signs and papilledema are common. Cranial nerve dysfunction and seizures may occur.

3. Other forms—Cutaneous forms are usually secondary to dissemination. Papules, pustules, and ulcerating nodules are typical. Bones (rarely joints) may be infected; osteolytic areas are seen, and the process may resemble osteosarcoma. Many other organs, especially the eyes, can be involved with dissemination.

B. Laboratory Findings

The CSF usually has a lymphocytic pleocytosis; it may be completely normal in immunosuppressed patients with meningeal infection. Direct microscopy may reveal organisms in sputum, CSF, or other specimens. The capsular antigen can be detected by latex agglutination or ELISA, which are both sensitive (> 90%) and specific. False-negative CSF tests occur rarely. Serum, CSF, and urine should be tested if this infection is suspected. The serum may be negative if the only organ infected is the lung. The organism grows well after several days on many routine media; for optimal culture, collecting and concentrating a large amount of CSF (10 mL) is recommended, because the number of organisms may be low.

C. Imaging

Radiographic findings are usually lower lobe infiltrates or nodular densities; less often effusions; and rarely cavitation, hilar adenopathy, or calcification. Single or multiple focal mass lesions (cryptococcoma) may be detected in the CNS on CT or MRI scan.

Differential Diagnosis

Cryptococcal meningitis may mimic tuberculosis, viral meningoencephalitis, meningitis due to other fungi, or a space-occupying CNS lesion. Lung infection is difficult to differentiate from many causes of pneumonia.

Complications

Hydrocephalus may be caused by chronic basilar meningitis. Symptomatic and recalcitrant intracranial hypertension is common. Significant pulmonary or osseous disease may accompany the primary infection or dissemination.

Treatment

Patients with symptomatic pulmonary disease should receive fluconazole for 3–6 months. All immunocompromised patients with cryptococcal pulmonary disease should have a lumbar puncture to rule out CNS infection; this should also be done...
for immunocompetent patients with cryptococcal antigen in the serum. Severely ill patients should receive amphotericin B (0.7 mg/kg/d). Meningitis is treated with amphotericin B (increase dose to 1 mg/kg/d) and flucytosine (100 mg/kg/d). This combination is synergistic and allows lower doses of amphotericin B to be used. Induction therapy is usually 2 weeks for CNS infections. Fluconazole can be substituted for flucytosine. After this, fluconazole alone (10 mg/kg/d) is maintained for 8 weeks and then continued at a reduced dose (determined by moderate serum levels) for an additional 6–12 months. Fluconazole is the preferred maintenance therapy to prevent relapses in high-risk (eg, HIV) patients. CSF antigen levels should be checked after 2 weeks of therapy. Intracranial hypertension is treated by frequent spinal taps or a lumbar drain.

**Prognosis**

Treatment failure, including death, is common in immunosuppressed patients, especially those with AIDS. Lifelong maintenance therapy may be required in these patients. Poor prognostic signs are the presence of extrameningeal disease, fewer than 20 cells/μL of initial CSF, and initial CSF antigen titer greater than 1:32.

**Histoplasmosis**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Residence in or travel to an endemic area.
- Pneumonia with flu-like illness.
- Hepatosplenomegaly, anemia, leukopenia if disseminated.
- Histoplasmal antigen in urine, blood, bronchoalveolar lavage fluid or CSF.
- Detection by staining the organism in smears or tissue, or by culture.

**General Considerations**

The dimorphic fungus *Histoplasma capsulatum* is found in the central and eastern United States (Ohio and Mississippi River valleys), Mexico, and most of South America. Soil contamination is enhanced by the presence of bat or bird feces. Infection is acquired by inhaling spores that transform into the pathogenic yeast form seen in infected tissues, especially within macrophages. Infections in endemic areas are very common at all ages and are usually asymptomatic. Over two-thirds of children are infected in these areas. Reactivation is rare in children, but occurs after treatment with immune suppressive agents, such as biological response modifiers and chemotherapy. Reactivation may occur years after primary infection. Reinfection also occurs. The extent of symptoms with primary infection or reinfection is influenced by the size of the infecting inoculum.

**Clinical Findings**

Because human-to-human transmission does not occur, infection requires exposure in the endemic area—usually within prior weeks or months. Congenital infection does not occur.

**A. Symptoms and Signs**

1. **Asymptomatic infection (90% of infections)**—Asymptomatic histoplasmosis is usually diagnosed by the presence of scattered calcifications in lungs or spleen and a positive skin test or serology. The calcification may resemble that caused by tuberculosis, but may be more extensive than the usual Ghon complex.

2. **Pneumonia**—Approximately 5% of patients have mild to moderate disease. The cause of this illness is usually not recognized as being histoplasma. Acute pulmonary disease may resemble influenza with fever, malaise, myalgia, arthralgia, and cough occurring 1–3 weeks after a heavy exposure (may be longer with less intense exposure). The subacute form resembles infections such as tuberculosis with cough, weight loss, night sweats, and pleurisy. Chronic disease is unusual in children. Physical examination may be normal, or rales may be heard. A small number of patients may have immune-mediated signs such as arthritis, pericarditis, and erythema nodosum. The usual duration of the disease is less than 2 weeks, followed by complete resolution, but symptoms may last several months before resolving without antifungal therapy.

3. **Disseminated infection (5% of infections)**—Fungemia during primary infection probably occurs in the first 2 weeks of all infections, including those with minimal symptoms. Transient hepatosplenomegaly may occur, but resolution is the rule in immunocompetent individuals. Heavy exposure, severe underlying pulmonary disease, and immunosuppression are risk factors for progressive reticuloendothelial cell infection with anemia, fever, weight loss, organomegaly, bone marrow involvement, and death. Dissemination may occur in otherwise
immunocompetent children; usually they are younger than age 2 years.

4. Other forms—Ocular involvement consists of multifocal choroiditis. This usually occurs in immunocompetent adults who exhibit other evidence of disseminated disease. Brain, pericardium, intestine, and skin (oral ulcers and nodules) are other sites that can be involved. Adrenal gland involvement is common with systemic disease.

B. Laboratory Findings

Routine tests are normal or nonspecific in the benign forms. Pancytopenia is present in many patients with disseminated disease. The diagnosis can be made by demonstrating the organism by histology or culture. Tissue yeast forms are small and may be mistaken for artifact. They are usually found in macrophages, occasionally in peripheral blood leukocytes in severe disease, but infrequently in sputum, urine, or CSF. Cultures of infected fluids or tissues may yield the organism after 1–4 weeks of incubation on fungal media, but even cultures of bronchoalveolar lavage or transbronchial biopsy specimens in immunocompromised patients are often negative (15%). Thus, bone marrow and tissue specimens are needed. Detection of histoplasmal antigen in blood, urine, CSF, and bronchoalveolar lavage fluid is the most sensitive diagnostic test (90% positive in the urine with disseminated disease, 75% positive with acute pneumonia), but false-negative results may occur. Both urine and serum should be tested for optimal results. The level of antigen correlates with the extent of the infection, and antigen levels can be used to follow the response to therapy and to indicate low-grade infection persisting after completion of therapy (eg, in a child with HIV infection).

Antibodies may be detected by immunodiffusion and complement fixation; the latter rises in the first 2–6 weeks of illness and falls thereafter unless dissemination occurs. Cross-reactions occur with some other endemic fungi. A single high titer or rising titer indicates a high likelihood of disease, but antigen detection has replaced serology as a rapid diagnostic test.

C. Imaging

Scattered pulmonary calcifications in a well child are typical of past infection. Bronchopneumonia (focal mid-lung infiltrates) occurs with acute disease, often with hilar and mediastinal adenopathy, occasionally with nodules, but seldom with effusion. Localized or patchy infiltrates occur in subacute disease. Apical cavitation occurs with chronic infection, often on the background of preexisting pulmonary infection.

Differential Diagnosis

Pulmonary disease resembles viral infection, other causes of community acquired pneumonia, tuberculosis, coccidiodomycosis, and blastomycosis. Systemic disease resembles disseminated fungal or mycobacterial infection, leukemia, histiocytosis, or cancer.

Treatment

Most patients with acute pulmonary disease will benefit from oral itraconazole. Those with subacute disease are generally better when the diagnosis is established, but if still symptomatic should receive oral therapy. Treatment with lipid formulation of amphotericin B (2–5 mg/kg/d) is indicated for severe pulmonary disease (diffuse radiographic involvement); disseminated disease; or when endovascular, CNS, or chronic pulmonary disease is present; and for children younger than age 1 year. Disseminated disease in infants may respond to as few as 10 days of amphotericin B, although 4–6 weeks is usually recommended. Patients with severe disease (especially pulmonary) may benefit from a short course of corticosteroid therapy. Surgical excision of chronic pulmonary lesions is rarely required. Itraconazole (3–5 mg/kg/d for 6–12 weeks; achieve peak serum level of > 1.0 mcg/mL) appears to be equivalent to amphotericin B therapy for mild disease and can be substituted in severe disease after a favorable initial (2 weeks) response to amphotericin B. With chronic pulmonary, CNS, or disseminated disease, prolonged therapy for at least a year should be considered.

Quantitation of fungal antigen is useful for directing therapy, and should be monitored for 1 year after successful treatment of severe disease. Relapse may occur in up to 15% of patients with treated chronic disease. Histoplasmosis can reactivate in previously infected individuals who subsequently become immunosuppressed. Chronically immunosuppressed patients (eg, those with HIV) may require lifelong maintenance therapy with itraconazole.

Prognosis

Patients with mild and moderately severe infections have a good prognosis. With early diagnosis and treatment, infants with disseminated disease usually recover; the prognosis worsens if the immune response is poor.

**Sporotrichosis**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Subacute cutaneous ulcers.
- New lesions appearing proximal to existing lesions along a draining lymphatic.
- Absence of systemic symptoms.
- Isolation of *Sporothrix schenckii* from wound drainage or biopsy.

**General Considerations**

Sporotrichosis is caused by *Sporothrix schenckii*, a dimorphic fungus present as a mold in soil, plants, and plant products from most areas of North and South America. Spores of the fungus can cause infection when they breach the skin at areas of minor trauma. Sporotrichosis has been transmitted from cutaneous lesions of pets.

**Clinical Findings**

Cutaneous disease is by far the most common manifestation. Typically at the site of inapparent skin injury, an initial papular lesion will slowly become nodular and ulcerate. Subsequent new lesions develop in a similar fashion proximally along lymphatics draining the primary lesion. This sequence of developing painless, chronic ulcers in a linear pattern is strongly suggestive of the diagnosis. Solitary lesions may exist and some lesions may develop a verrucous character. Systemic symptoms are absent and laboratory evaluations are normal, except for acute-phase reactants. The fungus rarely disseminates in immunocompetent hosts, but bone and joint infections have been described. Cavitary pneumonia is an uncommon manifestation when patients inhale the spores. Immunocompromised patients, especially those with HIV infection, may develop disseminated skin lesions and multiorgan disease with extensive pneumonia.

**Differential Diagnosis**

The differential diagnosis of nodular lymphangitis (sporotrichoid infection) includes other endemic fungi and some bacteria, especially atypical mycobacteria, pyoderma gangrenosum, nocardiosis, and syphilis. Diagnosis is made by culture. Biopsy of skin lesions will demonstrate a supplicative response with granulomas and provides the best source for laboratory isolation. Occasionally, the characteristic yeast will be seen in the biopsy.

**Treatment & Prognosis**

Treatment is with itraconazole (200 mg/d or 5 mg/kg/d) for 2–4 weeks after lesions heal, usually 3–6 months. Prognosis is excellent with lymphocutaneous disease in immunocompetent children. Pulmonary or osteoarticular disease, especially in immunocompromised individuals, requires longer therapy. Amphotericin B may be required for disseminated disease, CNS disease, and severe pulmonary disease. Surgical debridement may be required.

---

**PNEUMOCYSTIS AND OTHER OPPORTUNISTIC FUNGAL INFECTIONS**

The name of this category indicates that fungi that are normally not pathogenic, or do not cause severe disease, may do so when given the opportunity by changes in host defenses. They occur most commonly when patients are treated with corticosteroids, antineoplastic drugs, or radiation, thereby reducing the number or function of neutrophils and T cells. Inborn errors in immune function (combined immunodeficiency or chronic granulomatous disease) may also be complicated by these fungal infections. Opportunistic infections are facilitated by altering the normal flora with antibiotics and by disruption of mucous membranes or skin with antineoplastic therapy or indwelling lines and tubes.

Table 43–7 indicates that filamentous fungi are prominent causes of severe systemic fungal disease in immunocompromised patients. *Aspergillus* species (usually *fumigatus*) and Zygomycetes (usually Mucorales) cause subacute pneumonia and sinusitis and should be considered when these conditions do not respond to antibiotics in immunocompromised patients. *Aspergillus* species also commonly cause invasive disease in patients with chronic granulomatous disease. Mucormycosis is especially likely to produce severe sinusitis in patients with chronic acidosis, usually when the diabetes is poorly controlled. This fungus may invade orbit and cause brain infection. Mucormycosis also occurs in patients receiving iron chelation therapy. These fungal infections may disseminate widely. Imaging procedures may suggest the etiology, but they are best diagnosed by aspiration or biopsy of infected tissues. A characteristic CT finding is the “halo sign,” which is a...

ground-glass opacity surrounding a pulmonary nodule or mass. The “reversed halo sign” is a focal rounded ground-glass opacity surrounded by a crescent or complete ring of consolidation. Detection of mannose in blood and alveolar fluid is sometimes useful for the diagnosis of aspergillosis and detection of β-D-glucan in blood and alveolar fluid should be available for the diagnosis of other opportunistic pathogens.

Although *Cryptococcus* can cause disease in the immune competent hosts, it is more likely to be clinically apparent and severe in immunocompromised patients. This yeast causes pneumonia and is a prominent cause of fungal meningitis. *Candida* species in these patients cause fungemia and multiorgan disease, with lungs, esophagus, liver, and spleen frequently affected (see the section Disseminated *Candida* Infection earlier).
Opportunistic fungal infections should always be included in the differential diagnosis of unexplained fever or pulmonary infiltrates in immunocompromised patients. These pathogens should be aggressively pursued with imaging studies and with tissue sampling when clues are available. Cryptococcus and Aspergillus may be demonstrated with specific antigen tests. Opportunistic infections are difficult to treat because of the deficiencies in host immune response. Treatment should be undertaken with consultants who are expert in managing these infections. Voriconazole is the drug of choice for many mold infections, but both echinocandins and amphotericin B are good alternatives. Combinations of current antifungal drugs are being tested to improve the outcome. Many children who will have depressed phagocytic and T-cell–mediated immune function for long periods (eg, after hematopoietic stem cell transplants) should receive antifungal prophylaxis during the period of severe immune suppression, most often fluconazole or itraconazole. Very-low-birth-weight infants, who are at high risk for systemic Candida infection, often receive similar prophylaxis for prolonged periods.

Malassezia furfur is a yeast that normally causes the superficial skin infection known as tinea versicolor (see Chapter 15). This organism is considered an opportunist when it is associated with prolonged intravenous therapy, especially when central lines used for hyperalimentation. The yeast, which requires skin lipids for its growth, can infect lines when lipids are present in the infusate. Some species will grow in the absence of lipids. Unexplained fever and thrombocytopenia are common. Pulmonary infiltrates may be present. The diagnosis is facilitated by alerting the bacteriology laboratory to add olive oil to culture media. The infection will respond to removal of the line or the lipid supplement. Amphotericin B may hasten resolution.

**PNEUMOCYSTIS JIROVECI INFECTION**

**ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**

- Significant immunosuppression.
- Fever, tachypnea, cough, dyspnea.
- Hypoxemia; diffuse interstitial infiltrates.
- Detection of the organism in specimens of pulmonary origin.

**General Considerations**

Although classified as a fungus on the basis of structural and nucleic acid characteristics, Pneumocystis responds readily to antiprotozoal drugs and antifols. It is a ubiquitous pathogen. Initial infection is presumed to occur asymptptomatically via inhalation, usually in early childhood, and to become a clinical problem upon reactivation during immune suppression. There is evidence that person-to-person transmission may contribute to symptomatic disease in immune compromised individuals. In the normal host clinical disease rarely occurs. A syndrome of afebrile pneumonia similar to that caused by *Chlamydia trachomatis* in normal infants has been described, but its etiology is rarely appreciated. Whether by reactivation or new exposure, severe signs and symptoms occur chiefly in patients with abnormal T-cell function, such as hematologic malignancies and organ transplantation. *Pneumocystis* also causes severe pneumonia in patients with γ-globulin deficiency and is an AIDS-defining illness for children with advanced HIV infection. Prophylaxis usually prevents this infection (see Chapter 41).

Prolonged, high-dose corticosteroid therapy for any condition is a risk factor; onset of illness as steroids are tapered is a typical presentation. Severely malnourished infants with no underlying illness may also develop this infection, as can those with congenital immunodeficiency. The incubation period is usually at least 1 month after onset of immunosuppressive therapy.

Infection is generally limited to the lower respiratory tract. In advanced disease, spread to other organs occurs.

**Clinical Findings**

**A. Symptoms and Signs**

In most patients, a gradual onset of fever, tachypnea, dyspnea, and mild, nonproductive cough occurs over 1–4 weeks. Initially the chest is clear, although retractions and nasal flaring are present. At this stage the illness is nonspecific. Hypoxemia out of proportion to the clinical and
radiographic signs is an early finding; however, even minimally decreased arterial oxygen pressure values should suggest this diagnosis in immunosuppressed children. Tachypnea, nonproductive cough, and dyspnea progress. Respiratory failure and death occur without treatment. In some children with AIDS or severe immunosuppression from chemotherapy or organ transplantation, the onset may be abrupt and progression more rapid. Acute dyspnea with pleuritic pain may indicate the related complication of pneumothorax.

The general examination is unremarkable except for tachypnea and tachycardia; rales may be absent. There are no upper respiratory signs, conjunctivitis, organomegaly, enanthem, or rash.

B. Laboratory Findings

Laboratory findings reflect the individual child’s underlying illness and are not specific. Serum lactate dehydrogenase levels may be elevated markedly as a result of pulmonary damage. In moderately severe cases, the arterial oxygen pressure is less than 70 mm Hg or the alveolar-arterial gradient is less than 35 mm Hg.

C. Imaging

Early chest radiographs are normal. The classic pattern in later films is that of bilateral, interstitial, lower lobe alveolar disease starting in the perihilar regions, without effusion, consolidation, or hilar adenopathy. High-resolution CT scanning may reveal extensive ground-glass attenuation or cystic lesions. Older HIV-infected patients present with other patterns, including nodular infiltrates, lobar pneumonia, cavities, and upper lobe infiltrates.

D. Diagnostic Findings

Diagnosis requires finding characteristic round (6–8 mm) cysts in a lung biopsy specimen, bronchial brushings, alveolar washings, induced sputum, or tracheal aspirates. Tracheal aspirates are less sensitive, but are more rapidly and easily obtained. They are more often negative in children with leukemia compared with those with HIV infection; presumably, greater immunosuppression permits replication of a larger numbers of organisms. Because pneumonia in immunosuppressed patients may have many causes, negative results from tracheal secretions should prompt more aggressive diagnostic attempts. Bronchial washing using fiberoptic bronchoscopy is usually well tolerated and rapidly performed.

Several rapid stains—as well as the standard methenamine silver stain—are useful. The indirect fluorescent antibody method is most sensitive. These methods require competent laboratory evaluation, because few organisms may be present and many artifacts may be found.

Differential Diagnosis

In immunocompetent infants, C trachomatis pneumonia is the most common cause of the afebrile pneumonia syndrome described for Pneumocystis. In older immunocompromised children, the differential diagnosis includes influenza, respiratory syncytial virus, cytomegalovirus, adenovirus, and other viral infections; bacterial and fungal pneumonia; pulmonary emboli or hemorrhage; congestive heart failure; and Chlamydia pneumonieae and M pneumonieae infections. Lymphoid interstitial pneumonitis, which occurs in older infants with untreated HIV infection, is more indolent and the patient’s lactate dehydrogenase level is normal (see Chapter 41). Pneumocystis pneumonia is rare in children who are complying with prophylactic regimens.

Prevention

Children at high risk for developing Pneumocystis infection should receive prophylactic therapy. Children at risk include those with hematologic malignancies, children who for other reasons are receiving intensive chemotherapy or high-dose corticosteroids, and children with organ transplants or advanced HIV infection. All children born to HIV-infected mothers should receive prophylaxis against Pneumocystis starting at age 6 weeks until HIV infection has been ruled out or, if the infant is infected for the first year of life, when the patient’s immunologic status will determine additional prophylaxis (see Chapter 41). The prophylaxis of choice is trimethoprim-sulfamethoxazole (150 mg/m²/d of trimethoprim and 750 mg/m²/d of sulfamethoxazole) for 3 consecutive days of each week. Alternatives to this prophylaxis regimen are described in Chapter 41.

Treatment

A. General Measures

Supplemental oxygen and nutritional support may be needed. The patient should be in respiratory isolation.

B. Specific Measures

Trimethoprim-sulfamethoxazole (20 mg/kg/d of trimethoprim and 100 mg/kg/d of sulfamethoxazole in four divided doses intravenously or orally if well tolerated) is the treatment of choice. Improvement may not be seen for 3–5 days. Duration of treatment is 3 weeks in HIV-infected children. Methylprednisolone (2–4 mg/kg/d in four divided doses intravenously) should also be given to HIV-infected patients with moderate to severe infection (partial oxygen
pressure < 70 mm Hg or alveolar-arterial gradient > 35) for the first 5 days of treatment. The dosage is reduced by 50% for the next 5 days and further by 50% until antibiotic treatment is completed. If trimethoprim-sulfamethoxazole is not tolerated or there is no clinical response in 5 days, pentamidine isethionate (4 mg/kg once daily by slow intravenous infusion) should be given. Clinical efficacy is similar with pentamidine, but adverse reactions are more common. These reactions include dysglycemia, pancreatitis, nephrotoxicity, and leukopenia. Other effective alternatives utilized in adults include atovaquone, trimethoprim plus dapsone, and primaquine plus clindamycin.

**Prognosis**

The mortality rate is high in immunosuppressed patients who receive treatment late in the illness.

The rate of sexually transmitted infections (STIs) acquired during adolescence remains high despite widespread educational programs and increased access to health care. By senior year in high school, nearly half of youth will have had sexual intercourse. The highest age-specific rates for gonorrhea, chlamydia, and human papillomavirus (HPV) infection occur in adolescents and young adults (15–24 years of age). While this age group accounts for only 25% of the sexually active population, these youth account for almost half of the incident STI infections. Adolescents contract STIs at a higher rate than adults because of sexual risk taking, age-related biologic factors, and barriers to healthcare access. In every state and the District of Columbia, adolescents can provide consent for the diagnosis and treatment of STIs without parental consent. Only one state requires the notification of a parent in the event of a positive test; 17 others allow for the disclosure to a parent. In many states, adolescents can also provide consent for human immunodeficiency virus (HIV) counseling and testing. Since individual state laws vary, healthcare providers should be knowledgeable about the legal definitions regarding age of consent and confidentiality requirements in their respective state.

Providers should screen sexually experienced adolescents for STIs and use this opportunity to discuss risk reduction. Since not all adolescents receive regular preventive care, providers should consider using acute care visits to offer screening and education. Health education counseling should be nonjudgmental and appropriate for the developmental level, yet sufficiently thorough to identify risk behaviors because many adolescents may not readily acknowledge engaging in these behaviors.

ADOLESCENT SEXUALITY

The spectrum of sexual behavior includes holding hands and kissing, touching, mutual masturbation, oral-genital contact, and vaginal and anal intercourse. Each has its associated risks. A small, but statistically significant, trend has occurred in the epidemiology of sexual risk taking toward less sexual involvement and later onset of vaginal intercourse. The most recent Youth Risk Behavior Survey (2011) reports that 47% of high school students have had vaginal intercourse; 6% percent of teenagers initiated sex by age 13. Racial and gender differences exist; non-Hispanic black adolescents report a higher prevalence of sexual activity and an earlier age of initiation. Thirty-four percent of students had sex in the 3 months prior to the survey—48% of twelfth-graders and 21% of ninth-graders. Over 15% of students reported having had four or more lifetime sexual intercourse partners. Among those youth currently sexually active, 60% reported that either they or their partner had used a condom during their last sexual intercourse. Paradoxically, condom use decreases with age—63% of tenth-graders report condom use at their last intercourse compared with 56% of twelfth-graders. Substance use contributes to an increase in risky sexual activity and 22% of sexually active youth report that they used alcohol or drugs prior to their last intercourse.

Although there may be variations among groups of teens, oral sex is relatively common in adolescents with 55% and 54% of males and females, respectively, reporting oral sexual activity. Anal intercourse occurs in both heterosexual and homosexual populations. Adolescent development is a time of exploration, including one’s sexual orientation. Frequently, teenagers may not identify themselves as gay, lesbian, or bisexual; thus, sensitive, nonjudgmental history taking is necessary to elicit a history of same-sex partners. Adolescents struggling with their emerging sexual orientation and associated stigma may engage in sexual activity with partners of both sexes or use substances to cope, thereby impairing their decision-making abilities.

Centers for Disease Control and Prevention: Youth risk behavior surveillance—United States 2011. MMWR Surveill Summ 2012;61(SS–4) [PMID: 22673000].
RISK FACTORS

Certain behaviors and experiences put the adolescent at higher risk for developing STIs. These include early age at sexual debut, lack of condom use, multiple partners, prior STI, history of STI in a partner, and sex with a partner who is 3 or more years older. The type of sex affects risk as well, with intercourse being riskier than oral sex. Other risk-taking behaviors associated with STIs in adolescents are smoking, alcohol use, drug use, dropping out of school, pregnancy, and depression.

The adolescent female is especially predisposed to chlamydia, gonorrhea, and HPV infection because the cervix during adolescence has an exposed squamocolumnar junction. The rapidly dividing cells in this area are especially susceptible to microorganism attachment and infection. During early to midpuberty, this junction slowly invaginates as the uterus and cervix mature, and by the late teens to early 20s the squamocolumnar junction is inside the cervix.

PREVENTION OF SEXUALLY TRANSMITTED INFECTIONS

Efforts to reduce STI risk behavior should begin before the onset of sexual experimentation; first by helping youth personalize their risk for STIs and encouraging positive behaviors that minimize these risks, and then by enhancing communication skills with sexual partners about STI prevention, abstinence, and condom use.

Primary prevention focuses largely on education and risk-reduction techniques. It is essential to recognize that a key task of adolescence is developing a sexual identity. Teenagers are sexual beings that will decide if, when, and how they are going to initiate sexual involvement. Healthcare providers should routinely address sexuality as part of well-adolescent checkups. Being open and frank about the risks and benefits of each specific type of sexual activity will help youth think about their decision and the consequences. Although more than 90% of students have been taught about HIV infection and other STIs in school, adolescents still have a difficult time personalizing risk. Discussing prevalence, symptoms, and sequelae of STIs can raise awareness and help teenagers make informed decisions about initiating sexual activity and the use of safer sex techniques. Abstinence is theoretically an effective method of preventing sexually transmitted infections. However, many studies have failed to show sustainable protection. Making condoms available reiterates the message that safer sex is vital to health. Discussing condoms, dental dams, and the proper use of lubrication also facilitates safer sex practices. Condoms may prevent infections with HIV, HPV, gonorrhea, Chlamydia, and herpes simplex virus (HSV). They are probably effective in preventing other STIs as well.

Secondary prevention requires identifying and treating STIs (see the next section on Screening for Sexually Transmitted Infections) before infected individuals transmit infection to others. Access to confidential medical care is critical to this objective. Identifying and treating STIs in partners is essential in limiting the spread of these infections. Cooperation with the state or county health department is valuable, because these agencies assume the responsibility for locating the contacts of infected persons and ensuring appropriate treatment.

Tertiary prevention is directed toward complications of a specific illness. Examples of tertiary prevention would be treating pelvic inflammatory disease (PID) before infertility develops, following the serologic response to syphilis to prevent late-stage syphilis, treating cervicitis to prevent PID, or treating a chlamydial infection before epididymitis ensues.

Finally, preexposure vaccination against hepatitis B, hepatitis A, and HPV reduces the risk for these preventable STIs. All adolescents should have prior or current immunization against hepatitis B (see Chapter 10). However, because hepatitis B infection is frequently sexually transmitted, this vaccine is especially critical for all unvaccinated patients being evaluated for an STI. Hepatitis A vaccination is recommended for all individuals. Preexposure vaccination for HPV will decrease the risk for cervical dysplasia and cervical cancer in females, and decreases the risk for genital warts and both anal and oropharyngeal cancer in males and females, which can occur decades later (see Chapter 10).
The ability of the healthcare provider to obtain an accurate sexual history is crucial in prevention and control efforts. Teenagers should be asked open-ended questions about their sexual experiences to assess their risk for STIs. Questions must be clear to the youth, so choose language that the adolescent will understand. If the adolescent has ever engaged in sexual activity, the provider needs to determine what kind of sexual activity (mutual masturbation or oral, anal, or vaginal sex); whether it has been opposite-sex, same-sex, or both; whether birth control and condoms were used; and whether it has been consensual or forced. During the interview, the clinician should take the opportunity to discuss risk-reduction techniques regardless of the history obtained from the youth.

A routine laboratory screening process is warranted if the patient has engaged in intercourse, presents with STI symptoms, or reports a partner with an STI. The availability of nucleic acid amplification tests (NAATs), primarily for *Chlamydia* and *Neisseria gonorrhoeae*, has changed the nature of STI screening and intervention. These amplification tests are more than 95% sensitive and more than 99% specific, using either urine or cervical/urethral or vaginal swabs. Annual screening of all sexually active females aged 25 years or younger is recommended for *Chlamydia trachomatis* and *Neisseria gonorrhoeae*. Routine chlamydial testing should be considered for all adolescent males, especially for males who have sex with men, have new or multiple sex partners, or are in correctional facilities. For men who have sex with men, consideration should be given to testing oropharyngeal and rectal sites, as asymptomatic infections are common. Use of NAAT is recommended for samples from these sites, but such tests are not currently FDA-approved and providers must locate a laboratory that has performed the necessary validation studies.

Initial screening for urethritis in males begins with a physical examination. A first-catch urine sample (the first 10–40 mL of voided urine collected after not voiding for 2 hours) should be sent for *Chlamydia* and *N gonorrhoeae* testing if there are no signs (urethral discharge or lesions) or symptoms. With signs or symptoms of urethritis, a urethral swab should be sent to test for both *N gonorrhoeae* and *Chlamydia*. A wet mount preparation should then be done on a spun urine sample or from urethral discharge, evaluating for the presence of *Trichomonas vaginalis*. Newer technologies, such as enzyme-linked immunoassays (ELA) and NAAT testing, have become available that allow greater sensitivity and specificity in making the diagnosis of *T vaginalis* in males and females.

Screening asymptomatic females is more complicated because a variety of approaches are available. Generally, either a first-void urine specimen, a cervical swab, or a vaginal swab is used to screen for *Chlamydia* and *N gonorrhoeae* by NAAT. Any vaginal discharge symptoms should include evaluation of wet mount of vaginal secretions to check for bacterial vaginosis and trichomoniasis, and a potassium hydroxide (KOH) preparation to screen for yeast infections. The Papanicolaou (Pap) smear serves to evaluate the cervix for the presence of dysplasia. The first Pap smear should be performed at age 21 years and then every 3 years. HPV typing is not recommended.

In urban areas with a relatively high rate of syphilis and in males who have sex with men, a screening test should be drawn yearly or more frequently if higher risk encounters are more frequent. RPR and HIV antibody tests should be done in all individuals in whom a concomitant STI is present.

The most common symptoms in males are dysuria and penile discharge resulting from urethral inflammation. However, providers should be aware that many urethral infections are asymptomatic. Less common symptoms are scrotal pain, hematuria, proctitis, and pruritus in the pubic region. Signs include epididymitis, orchitis, and urethral discharge. Rarely do males develop systemic symptoms. However, especially for MSM, but for any sexually active adolescent at risk for HIV infection who presents with nonspecific viral symptoms, acute HIV seroconversion illness should be considered in the differential diagnoses. For females, the most common symptoms are vaginal discharge and dysuria. Again, infection may be asymptomatic. Vaginal itching and irregular menses or spotting are also common. Abdominal pain, fever, and vomiting, although less common and specific, are signs of PID. Pain in the genital region and dyspareunia may be present.
Signs that can be found in both males and females with an STI include genital ulcerations, adenopathy, and genital warts.

THE MOST COMMON ANTIBIOTIC-RESPONSIVE SEXUALLY TRANSMITTED INFECTIONS

C. trachomatis and N. gonorrhoeae are STIs that are epidemic in the United States and are readily treated when appropriate antibiotics are administered in a timely fashion.

CHLAMYDIA TRACHOMATIS INFECTION

General Considerations

C. trachomatis is the most common bacterial cause of STIs in the United States. In 2011, over 1.4 million cases in adolescents and young adults were reported to the CDC. C. trachomatis is an obligate intracellular bacterium that replicates within the cytoplasm of host cells. Destruction of Chlamydia-infected cells is mediated by host immune responses.

Clinical Findings

A. Symptoms and Signs

Clinical infection in females manifests as dysuria, urethritis, vaginal discharge, cervicitis, irregular vaginal bleeding, or PID. The presence of mucopus at the cervical os (mucopurulent cervicitis) is a sign of chlamydial infection or gonorrhea. Chlamydial infection is asymptomatic in 75% of females.

Chlamydial infection may be asymptomatic in 70% of males or manifest as dysuria, urethritis, or epididymitis. Some patients complain of urethral discharge. On clinical examination, a clear white discharge may be found after milking the penis. Proctitis or proctocolitis from Chlamydia may occur in adolescents practicing receptive anal intercourse.

B. Laboratory Findings

NAAT is the most sensitive (92%-99%) way to detect Chlamydia. Enzyme-linked immunosorbent assay (ELISA) or direct fluorescent antibody (DFA) tests are less sensitive, but may be the only testing option in some centers.

A cervical or vaginal swab, using the manufacturer’s swab provided with the specific test, or first-void urine specimen, should be obtained. For urine screening, yields of testing are maximized when collecting between 10 and 20 mL of urine and ensuring that patient has not voided for 2 hours. Often a single swab can be used to collect both the Chlamydia and N. gonorrhoeae specimen. To optimize detection of Chlamydia from the cervix, columnar cells need to be collected by inserting the swab in the os and rotating it 360 degrees. NAAT is not licensed for rectal samples but some laboratories have validated testing on rectal specimens for C. trachomatis. Thus, when a rectal specimen is obtained, this must often be evaluated by less sensitive culture methods unless there is access to a laboratory that has validated Chlamydia NAAT for nongenital sites.

The first-void urine test for leukocyte esterase was previously used for screening asymptomatic, sexually active males. Because of the high false-positive rate, this screening technique is not commonly used. In symptomatic males, examination of the urine sediment for white blood cells (WBCs) provides a screen for urethritis, although it is often impractical to perform in a clinical setting.

In general, a first-void urine sample, or urethral swab for NAAT, should be obtained at least annually. Some studies suggest that more frequent screenings—every 6 months—in higher-prevalence populations can decrease the rate of chlamydial infection. For both males and females, testing urine allows for more frequent screening and simplifies screening in large group settings, such as schools and correctional facilities.

Complications

Epididymitis is a complication in males. Reiter syndrome occurs in association with chlamydial urethritis. This should be suspected in male patients who are sexually active and present with low back pain (sacroilitis), arthritis (polyarticular), characteristic mucocutaneous lesions, and conjunctivitis. PID is an important complication in females.

Treatment

Infected patients and their contacts, regardless of the extent of signs or symptoms, need to receive treatment (Table 44–1). Reinfection caused by failure of contacts to receive treatment or the initiation of sexual activity with a new infected partner puts the adolescent at high risk of acquiring a repeat chlamydial infection within several months of the first infection. Because of this increased risk, all infected females and males should be retested approximately 3 months after treatment.

| Scabies | Permethrin cream 5%; apply to entire body from the neck down, wash off after 8–14 h or Ivermectin, 200 mcg/kg orally, repeat in 2 wk | Safe [B] Contraindicated [C] |

| Alternative regimen | Lindane (1%): apply to entire body from neck down, wash off after 8 h | Contraindicated [C] |

**IM, intramuscular; IV, intravenous; NAAT, nucleic acid amplification test.**

*FDA use in pregnancy ratings: [A] Controlled studies show no risk. Adequate, well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester of pregnancy. [B] No evidence of risk in humans. Adequate, well-controlled studies in pregnant women have not shown increased risk of fetal abnormalities despite adverse findings in animals, in the absence of adequate human studies, animal studies show no fetal risk. The chance of fetal harm is remote but remains a possibility. [C] Risk cannot be ruled out. Adequate, well-controlled human studies are lacking, and animal studies have shown a risk to the fetus or are lacking as well. There is a chance of fetal harm if the drug is administered during pregnancy, but the potential benefits outweigh the potential risk. [D] Positive evidence of risk. Studies in humans, or investigational or postmarketing data, have demonstrated fetal risk. Nevertheless, potential benefits from the use of the drug may outweigh the potential risk. For example, the drug may be acceptable if needed in a life-threatening situation or serious disease for which safer drugs cannot be used or are ineffective. [X] Contraindicated in pregnancy. Studies in animals or humans, or despite adverse findings in animals, or investigational or postmarketing reports have demonstrated positive evidence of fetal abnormalities or risk that clearly outweighs any possible benefit to the patient. Single daily dose (3–5 mg/kg) IV can be substituted.*

*Doxycycline is contraindicated in pregnancy. Alternative therapies during pregnancy which include erythromycin, azithromycin, and amoxicillin are not as effective, but are clinically useful if the recommended regimens cannot be used due to allergy or pregnancy.*

*Bedding and clothing need to be decontaminated by washing in hot water or by dry cleaning. Regimen may be repeated in 1 week if complete response is not achieved.*
NEISSERIA GONORRHOEAE INFECTION

General Considerations

Gonorrhea is the second most prevalent bacterial STI in the United States, where an estimated 700,000 new N gonorrhoeae infections occur each year. While the overall rates have decreased, gonorrhea rates continue to be highest among adolescents and young adults. Among females in 2011, 15- to 19-year-olds and 20- to 24-year-olds had the highest rates of gonorrhea; among males, 20- to 24-year-olds had the highest rate.

Sites of infection include the cervix, urethra, rectum, and pharynx. In addition, gonorrhea is a cause of PID. Humans are the natural reservoir. Gonococci are present in the exudate and secretions of infected mucous membranes.

Clinical Findings

A. Symptoms and Signs

In uncomplicated gonococcal cervicitis, females are symptomatic 23%–57% of the time, presenting with vaginal discharge and dysuria. Urethritis and pyuria may also be present. Mucopurulent cervicitis with a yellowish discharge may be found, and the cervix may be edematous and friable. Other symptoms include abnormal menstrual periods and dyspareunia. Approximately 15% of females with endocervical gonorrhea have signs of involvement of the upper genital tract. Compared with chlamydial infection, pelvic inflammation with gonorrhea has a shorter duration, but an increased intensity of symptoms, and is more often associated with fever. Symptomatic males usually have a yellowish-green urethral discharge and burning on urination, but most males (55%–67%) with N gonorrhoeae are asymptomatic. Both males and females can develop gonococcal proctitis and pharyngitis after appropriate exposure.

B. Laboratory Findings

A first void urine sample or cervical or vaginal swab from females should be sent for NAAT. Culture or NAAT for N gonorrhoeae in males can be achieved with a swab of the urethra or first-void urine. Urethral culture is less sensitive (85%) compared with the 95%–99% sensitivity using NAAT methods on either urethral or urine specimens. Gram stain of urethral discharge showing gram-negative intracellular diplococci indicates gonorrhea in a male.

If proctitis is present, appropriate cultures should be obtained and treatment for both gonorrhea and chlamydial infection given. If oral exposure to gonorrhea is suspected, cultures should be taken and the patient given empiric treatment. If there is access to a laboratory that has validated NAAT for oropharyngeal or rectal specimens, this will substantially increase detection over culture methods.

Differential Diagnosis

Gonococcal pharyngitis needs to be differentiated from pharyngitis caused by streptococcal infection, herpes simplex, adenovirus, and infectious mononucleosis. Chlamydial infection needs to be differentiated from gonococcal infection.

Complications

Disseminated gonococcal infection occurs in a minority (0.5%–3%) of patients with untreated gonorrhea. Hematogenous spread most commonly causes arthritis and dermatitis. The joints most frequently involved are the wrist, metacarpophalangeal joints, knee, and ankle. Skin lesions are typically tender, with hemorrhagic or necrotic pustules or bullae on an erythematous base occurring on the distal extremities. Disseminated disease occurs more frequently in females than in males. Risk factors include pregnancy and gonococcal pharyngitis. Gonorrhea is complicated occasionally by perihepatitis.

Treatment (see Table 44–1)

In 2010, the CDC made two significant changes to gonorrhea treatment recommendations: dual treatment and treatment with ceftriaxone 250 mg IM regardless of anatomic site involved. These changes reflect increasing resistance to cephalosporins; the frequency of coinfection with Chlamydia; and the need to increase consistency of treatment regimens.

CDC guidelines also state that N gonorrhoeae and C trachomatis do not require tests of cure when they are treated with first-line medications, unless the patient remains symptomatic. If retesting is indicated, it should be delayed for 1 month after completion of therapy if NAATs are used. Retesting might also be considered for sexually active adolescents likely to be reinfected. Due to increasing resistance of N gonorrhoeae to cephalosporins, providers considering treatment failure should also obtain a gonorrhea culture to assess for antibiotic resistance. Patients should be advised to abstain from sexual intercourse until both they and their partners have completed a course of treatment. Treatment for disseminated disease may require hospitalization. Quinolones should no longer be used to treat gonorrhea due to high levels of quinolone resistance in all populations in the United States. Failure of initial treatment should prompt reevaluation of the patient and consideration of retreatment with ceftriaxone.

The patient presenting with an STI usually has one or more of the signs or symptoms described in this section. Management considerations for STIs include assessing the patient’s adherence to therapy and ensuring follow-up, treating STIs in partners, and determining pregnancy risk. Treatment of each STI is detailed in Table 44–1.

## CERVICITIS

### General Considerations

In most cases of cervicitis no organism is isolated. The most common causes include *C trachomatis* or *N gonorrhoeae*. HSV, *T vaginalis*, and *Mycoplasma genitalium* are less common causes. Bacterial vaginosis is now recognized as a cause of cervicitis. Cervicitis can also be present without an STI.

### Clinical Findings

#### A. Symptoms and Signs

Two major diagnostic signs characterize cervicitis: (1) purulent or mucopurulent endocervical exudate visible in the endocervical canal or on an endocervical swab and (2) easily induced bleeding with the passage of a cotton swab through the cervical os. Cervicitis is often asymptomatic, but many patients with cervicitis have an abnormal vaginal discharge or postcoital bleeding.

#### B. Laboratory Findings

Although endocervical Gram stain may show an increased number of polymorphonuclear leukocytes, this finding has a low positive predictive value and is not recommended for diagnosis. Patients with cervicitis should be tested for *C trachomatis*, *N gonorrhoeae*, and trichomoniasis by using the most sensitive and specific tests available at the site.

### Complications

Persistent cervicitis is difficult to manage and requires reassessment of the initial diagnosis and reevaluation for possible re-exposure to an STI. Cervicitis can persist despite repeated courses of antimicrobial therapy. Presence of a large ectropion can contribute to persistent cervicitis.

### Treatment

Empiric treatment for both gonorrhea and chlamydial infection is recommended because coinfection is common. If the patient is asymptomatic except for cervicitis, then treatment may wait until diagnostic test results are available (see Table 44–1). Follow-up is recommended if symptoms persist.

Patients should be instructed to abstain from sexual intercourse until they and their sex partners are cured and treatment is completed.

## PELVIC INFLAMMATORY DISEASE

### General Considerations

Pelvic inflammatory disease (PID) is defined as inflammation of the upper female genital tract and may include endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. It is the most common gynecologic disorder necessitating hospitalization for female patients of reproductive age in the United States. Over 1 million females develop PID annually, 60,000 are hospitalized, and over 150,000 are evaluated in outpatient settings. The incidence is highest in the teen population. Teenage girls who are sexually active have a high risk (1 in 8) of developing PID, whereas women in their 20s have one-tenth the risk. Predisposing risk factors include multiple sexual partners, younger age of initiating sexual intercourse, prior history of PID, and lack of condom use. Lack of protective antibody from previous exposure to sexually transmitted organisms and cervical ectopy contribute to the development of PID. Many adolescents with subacute or asymptomatic infection are never identified.

PID is a polymicrobial infection. Causative agents include *N gonorrhoeae*, *Chlamydia*, anaerobic bacteria that reside in the vagina, and genital mycoplasmas. Vaginal douching and other mechanical factors such as older intrauterine devices or prior gynecologic surgery increase the risk of PID by providing access of lower genital tract organisms to pelvic organs. Recent menses and bacterial vaginosis have been associated with the development of PID.

### Clinical Findings

#### A. Symptoms and Signs

PID may be challenging to diagnose because of the wide variation in the symptoms and signs. No single historical, clinical, or laboratory finding has both high sensitivity and specificity for the diagnosis. Diagnosis of PID is usually made clinically (Table 44–2). Typical patients have lower abdominal pain, pelvic pain, or dysuria. However, the patient may be febrile or have additional systemic symptoms such as nausea or vomiting. Vaginal discharge is variable. Cervical motion tenderness, uterine or adnexal tenderness, or signs of peritonitis are often present. Mucopurulent cervicitis is present in 50% of patients. Tubo-ovarian abscesses can often be detected by careful physical examination (feeling a mass or fullness in the adnexa).
should be screened for HIV infection.

N gonorrhoeae and should be tested for and abdominal ultrasound. All women who have acute PID with PID. Transvaginal ultrasound is more sensitive than ovarian abscesses, which are found in almost 20% of teens Pelvic ultrasonography also is helpful in detecting tubo-

The clinical diagnosis of PID has a positive predictive value of salpingitis as some women may only have endometritis. Undergoing laparoscopy who do not have visual evidence torsion. Endometrial biopsy should be performed in women PID from an ectopic pregnancy, ovarian cysts, or adnexal

C. Diagnostic Studies

Laparoscopy is the gold standard for detecting salpingitis. It is used if the diagnosis is in question or to help differentiate PID from an ectopic pregnancy, ovarian cysts, or adnexal torsion. Endometrial biopsy should be performed in women undergoing laparoscopy who do not have visual evidence of salpingitis as some women may only have endometritis. The clinical diagnosis of PID has a positive predictive value for salpingitis of 65%–90% in comparison with laparoscopy. Pelvic ultrasonography also is helpful in detecting tubo-ovarian abscesses, which are found in almost 20% of teens with PID. Transvaginal ultrasound is more sensitive than abdominal ultrasound. All women who have acute PID should be tested for N gonorrhoeae and C trachomatis and should be screened for HIV infection.

### Table 44–2. Diagnostic criteria for pelvic inflammatory disease.

<table>
<thead>
<tr>
<th>Minimum criteria</th>
</tr>
</thead>
<tbody>
<tr>
<td>Empiric treatment of PID should be initiated in sexually active young women and others at risk for sexually transmitted infections if one or more of the following minimum criteria are present:</td>
</tr>
<tr>
<td>• They are experiencing pelvic or lower abdominal pain and no other cause(s) for the illness can be identified</td>
</tr>
<tr>
<td>• Cervical motion tenderness or uterine tenderness or adnexal tenderness</td>
</tr>
</tbody>
</table>

Additional supportive criteria

- Oral temperature > 38.3°C (101°F)
- Abnormal cervical or vaginal mucopurulent discharge
- Presence of abundant white blood cells on microscopic evaluation of vaginal secretions diluted in saline
- Elevated erythrocyte sedimentation rate or elevated C-reactive protein
- Laboratory documentation of infection with *Neisseria gonorrhoeae* or *Chlamydia trachomatis*

Definitive criteria (selected cases)

- Histopathologic evidence of endometritis on endometrial biopsy
- Tubo-ovarian abscess on sonography or other radiologic tests
- Laparoscopic abnormalities consistent with PID

Adapted, with permission, from Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines 2010. MMWR Recomm Rep 2010;59(RR-12).

### Differential Diagnosis

Differential diagnosis includes other gynecologic illnesses (ectopic pregnancy, threatened or septic abortion, adnexal torsion, ruptured and hemorrhagic ovarian cysts, dysmenorrhea, endometriosis, or mittelschmerz), gastrointestinal illnesses (appendicitis, cholecystitis, hepatitis, gastroenteritis, or inflammatory bowel disease), and geniturinary illnesses (cystitis, pyelonephritis, or urinary calculi).

### Complications

Scarring of the fallopian tubes is one of the major sequelae of PID. After one episode of PID, 17% of patients become infertile, 17% develop chronic pelvic pain, and 10% will have an ectopic pregnancy. Infertility rates increase with each episode of PID; three episodes of PID result in a 73% infertility rate. Duration of symptoms appears to be the largest determinant of infertility. Hematogenous or lymphatic spread of organisms from the fallopian tubes rarely causes inflammation of the liver capsule (perihepatitis) resulting in symptoms of pleuritic right upper quadrant pain and elevation of liver function tests.

### Treatment

The objectives of treatment are both to achieve a clinical cure and to prevent long-term sequelae. There are no differences in short- and long-term clinical and microbiologic response rates between parenteral and oral therapy. PID is frequently managed at the outpatient level, although some clinicians argue that all adolescents with PID should be hospitalized because of the rate of complications. Severe systemic symptoms and toxicity, signs of peritonitis, inability to take fluids, pregnancy, nonresponse or intolerance of oral antimicrobial therapy, and tubo-ovarian abscess favor hospitalization. In addition, if the healthcare provider believes that the patient will not adhere to treatment, hospitalization is warranted. Pregnant women with PID should be admitted to hospital and treated with parenteral antibiotics to reduce the increased risk of morbidity. Surgical drainage may be required for adequate treatment of tubo-ovarian abscesses.

The antibiotic regimens described in Table 44–1 are broad spectrum to cover the numerous microorganisms associated with PID. All treatment regimens should be effective against *N gonorrhoeae* and *C trachomatis* because negative endocervical screening tests do not rule out upper reproductive tract infection with these organisms. Outpatient treatment should be reserved for compliant patients who have classic signs of PID without systemic symptoms. Patients with PID who receive outpatient treatment should be reexamined within 24–48 hours, with phone contact in the interim, to detect persistent disease or treatment failure. Patients should have substantial improvement within 48–72 hours. An adolescent
should be reexamined 7–10 days after the completion of therapy to ensure the resolution of symptoms.

URETHRITIS

General Considerations

The most common bacterial causes of urethritis in males are N gonorrhoeae and C trachomatis. Additionally, T vaginalis, HSV, Ureaplasma urealyticum, and M genitalium cause urethritis. Approximately 15%–25% of nongonococcal, nonchlamydial urethritis can be attributed to either M genitalium or U urealyticum. Coliforms may cause urethritis in males practicing insertive anal intercourse. Mechanical manipulation or contact with irritants can also cause transient urethritis. It is important to recognize that urethritis in both males and females is frequently asymptomatic.

Females often present with symptoms of a urinary tract infection and "sterile pyuria" (no enteric bacterial pathogens isolated), which reflects urethritis caused by the organisms described above.

Clinical Findings

A. Symptoms and Signs

If symptomatic, males present most commonly with a clear or purulent discharge from the urethra, dysuria, or urethral pruritus. Hematuria and inguinal adenopathy can occur. Most infections caused by C trachomatis and T vaginalis are asymptomatic, while 70% of males with M genitalium and 23%–90% with gonococcal urethritis are symptomatic.

B. Laboratory Findings

In a symptomatic male a positive leukocyte esterase test on first-void urine, or microscopic examination of first-void urine demonstrating more than 10 WBCs per high-power field, is suggestive of urethritis. Gram stain of urethral secretions demonstrating more than 5 WBCs per high-power field is also suggestive. Gonococcal urethritis is established by documenting the presence of WBCs containing intracellular gram-negative diplococci. Urethral swab or first-void urine for NAAT should be sent to the laboratory to detect N gonorrhoeae and C trachomatis. Evaluation for T vaginalis should be considered as newer technologies increase the sensitivity and specificity of detecting T vaginalis over wet mount. Microscopic examination of urethral discharge is not a sensitive test. Specific NAAT testing of urine is available for Mycoplasma and Ureaplasma, though it is not often clinically utilized.

Complications

Complications include recurrent or persistent urethritis, epididymitis, prostatitis, or Reiter syndrome.

Treatment (See Table 44–1)

Patients with objective evidence of urethritis should receive empiric treatment for gonorrhea and chlamydial infection, ideally directly observed in the office. Some data suggest better outcomes for treatment of Mycoplasma genitalium with azithromycin. If the infection is unresponsive to initial treatment and the infection is NAAT-negative, trichomoniasis should be ruled out and nongonococcal, nonchlamydial urethritis should be suspected and treated appropriately. Patients should be instructed to return for evaluation if symptoms persist or recur after completion of initial empiric therapy. Symptoms alone, without documentation of signs or laboratory evidence of urethral inflammation, are not a sufficient basis for retreatment. Sexual partners should either be evaluated or treated for gonorrhea and chlamydial infection.

EPIDIDYMITIS

General Considerations

Epididymitis in a male who is sexually active is most often caused by C trachomatis or N gonorrhoeae. Epididymitis caused by Escherichia coli occurs among males who are the insertive partners during anal intercourse and in males who have urinary tract abnormalities.

Clinical Findings

A. Symptoms and Signs

Epididymitis presents as a constellation of pain, swelling, and inflammation of the epididymis. In many cases, the testis is also involved.
Sexually Transmitted Infections

B. Laboratory and Diagnostic Studies
Diagnosis is generally made clinically. Color Doppler ultrasound can help make the diagnosis. Although often not available, radionuclide scanning of the scrotum is the most accurate method of diagnosis. Laboratory evaluation is identical to evaluation for suspected urethritis.

Differential Diagnosis
Acute epididymitis must be distinguished from orchitis due to infarct, testicular torsion, viral infection, testicular cancer, tuberculosis, or fungal infection.

Complications
Infertility is rare, and chronic local pain is uncommon.

Treatment
Empiric therapy (see Table 44–1) is indicated before culture results are available. As an adjunct to therapy, bed rest, scrotal elevation, and analgesics are recommended until fever and local inflammation subside. Lack of improvement of swelling and tenderness within 3 days requires reevaluation of both the diagnosis and therapy. Sex partners should be evaluated and treated for gonorrhea and chlamydial infections.

PROCTITIS, PROCTOCOLITIS, & ENTERITIS

General Considerations
Proctitis occurs predominantly among persons who participate in anal intercourse. Enteritis occurs among those whose sexual practices include oral-fecal contact. Proctocolitis can be acquired by either route depending on the pathogen. Common sexually transmitted pathogens causing proctitis or proctocolitis include C trachomatis (including lymphogranuloma venereum [LGV] serovars), Treponema pallidum, HSV, N gonorrhoeae, Giardia lamblia, and enteric organisms. As many as 85% of rectal infections with N gonorrhoeae and C trachomatis are asymptomatic. The presence of symptomatic or asymptomatic proctitis may facilitate the transmission of HIV infection.

Clinical Findings
A. Symptoms and Signs
Proctitis, defined as inflammation limited to the distal 10–12 cm of the rectum, is associated with anorectal pain, tenesmus, and rectal discharge. Acute proctitis among persons who have recently practiced receptive anal intercourse is most often sexually transmitted. The symptoms of proctocolitis combine those of proctitis, plus diarrhea or abdominal cramps (or both), because of inflamed colonic mucosa more than 12 cm from the anus. Enteritis usually results in diarrhea and abdominal cramping without signs of proctitis or proctocolitis.

VAGINAL DISCHARGE
Adolescent girls may have a normal physiologic leukorrhea, secondary to turnover of vaginal epithelium. Infectious causes of discharge include T vaginalis, C trachomatis, N gonorrhoeae, and bacterial vaginosis pathogens. Candidiasis is a yeast infection that produces vaginal discharge, but is not usually sexually transmitted. Vaginitis is characterized by vaginal discharge, vulvar itching, and irritation, and sometimes with vaginal odor. Discharge may be white, gray, or yellow. Physiologic leukorrhea is usually white, homogeneous, and not associated with itching, irritation, or foul odor. Mechanical, chemical, allergic, or other noninfectious irritants of the vagina may cause vaginal discharge.

1. Bacterial Vaginosis
General Considerations
Bacterial vaginosis is a polymicrobial infection of the vagina caused by an imbalance of the normal bacterial vaginal flora. The altered flora has a paucity of hydrogen peroxide–producing lactobacilli and increased concentrations of anaerobic bacteria (Mobiluncus sp), and Gardnerella vaginalis, Ureaplasma, and Mycoplasma. It is unclear whether bacterial vaginosis is sexually transmitted, but it is associated...
with having multiple sex partners and women with bacterial vaginosis are at increased risk for other STIs.

## Clinical Findings
### A. Symptoms and Signs
The most common symptom is a copious, malodorous, homogeneous thin gray-white vaginal discharge. Patients may report vaginal itching or dysuria. A fishy odor may be most noticeable after intercourse or during menses, when the high pH of blood or semen volatilizes the amines.

## B. Laboratory Findings
Bacterial vaginosis is most often diagnosed by the use of clinical criteria, which include (1) presence of thin, white discharge that smoothly coats the vaginal walls, (2) fishy (amine) odor before or after the addition of 10% KOH (whiff test), (3) pH of vaginal fluid greater than 4.5 determined with narrow-range pH paper, and (4) presence of “clue cells” on microscopic examination. Clue cells are squamous epithelial cells that have multiple bacteria adhering to them, making their borders irregular and giving them a speckled appearance. Diagnosis requires three out of four criteria, although many female patients who fulfill these criteria have no discharge or other symptoms.

## Complications
Bacterial vaginosis during pregnancy is associated with adverse outcomes such as premature labor, preterm delivery, intraamniotic infection, and postpartum endometritis. In the nonpregnant individual, it may be associated with PID and urinary tract infections.

## Treatment
All female patients who have symptomatic disease should receive treatment to relieve vaginal symptoms and signs of infection (see Table 44–1). Pregnant patients should receive treatment to prevent adverse outcomes of pregnancy. Treatment for patients who do not complain of vaginal discharge or itching, but who demonstrate bacterial vaginosis on routine pelvic examination, is unclear. Because some studies associate bacterial vaginosis and PID, the recommendation is to have a low threshold for treating asymptomatic bacterial vaginosis. Follow-up visits are unnecessary if symptoms resolve. Recurrence of bacterial vaginosis is not unusual. Follow-up examination 1 month after treatment for high-risk pregnant patients is recommended.

Males do not develop infection equivalent to bacterial vaginosis and are often asymptomatic. Treatment of male partners has no effect on the course of infection in females although treatment is recommended for female partners.

---

**2. Trichomoniasis**

### General Considerations
Trichomoniasis is caused by *T. vaginalis*, a flagellated protozoan that infects 5–7 million people annually in the United States.

## Clinical Findings
### A. Symptoms and Signs
Fifty percent of females with trichomoniasis develop a symptomatic vaginitis with vaginal itching, a green-gray malodorous frothy discharge, and dysuria. Occasionally postcoital bleeding and dyspareunia may be present. The vulva may be erythematous and the cervix friable.

## B. Laboratory Findings
Mixing the discharge with normal saline facilitates detection of the flagellated protozoan on microscopic examination (wet preparation). This has a sensitivity of only 60%–70% even with immediate evaluation of the slide to achieve optimal results. Culture and NAAT testing are available when the diagnosis is unclear. NAAT tests are sensitive, but expensive, and not readily available. Two FDA-approved, point-of-care antigen-based detection assays for *T. vaginalis* are available, but false positive results are problematic in low disease prevalence populations. Both antigen assays are performed on vaginal secretions and have a sensitivity greater than 83% and a specificity greater than 97%. Trichomonal urethritis frequently causes a positive urine leukocyte esterase test and WBCs on urethral smear.

## Complications
Male partners of females diagnosed with trichomoniasis have a 22% chance of having trichomoniasis. Half of males with trichomoniasis will have urethritis. *Trichomonas* infection in females has been associated with adverse pregnancy outcomes. Rescreening for *T. vaginalis* at 3 months following initial infection is recommended for women due to the high rate of reinfection.

## Treatment
See Table 44–1 for treatment recommendations.

---

3. Vulvovaginal Candidiasis

**General Considerations**

Vulvovaginal candidiasis is caused by *Candida albicans* in 85%–90% of cases. Most females will have at least one episode of vulvovaginal candidiasis in their lifetime, and almost half will have two or more episodes. The highest incidence is between ages 16 and 30 years. Predisposing factors include recent use of antibiotics, diabetes, pregnancy, and HIV. Risk factors include vaginal intercourse, especially with a new sexual partner, use of oral contraceptives, and use of spermicide. This disease is usually caused by unrestrained growth of *Candida* that normally colonizes the vagina asymptptomatically or is infected secondarily from *Candida* present in the GI tract. Recurrences reflect reactivation of colonization.

**Clinical Findings**

**A. Symptoms and Signs**

Typical symptoms include pruritus and a white, cottage cheese-like vaginal discharge without odor. The itching is more common midcycle and shortly after menses. Other symptoms include vaginal soreness, vulvar burning, vulvar edema and redness, dyspareunia, and dysuria (especially after intercourse).

**B. Laboratory Findings**

The diagnosis is usually made by visualizing yeast or pseudohyphae with 10% KOH (90% sensitive) or Gram stain (77% sensitive) in the vaginal discharge. Fungal culture can be used if symptoms and microscopy are not definitive or if disease is unresponsive or recurrent. However, culture is not very specific as colonization is common in asymptomatic females. Vaginal pH is normal with yeast infections.

**Complications**

The only complication of vulvovaginal candidiasis is recurrent infections. Most females with recurrent infection have no apparent predisposing or underlying conditions.

**Treatment**

Short-course topical formulations effectively treat uncomplicated vaginal yeast infections (see Table 44–1). The topically appliedazole drugs are more effective than nystatin. Treatment with azoles results in relief of symptoms and negative cultures in 80%–90% of patients who complete therapy. Oral fluconazole as a one-time dose is an effective oral treatment. Patients should be instructed to return for follow-up visits only if symptoms persist or recur. Six-month prophylaxis regimens have been effective in many female patients with persistent or recurrent yeast infection. Recurrent disease is usually due to *C albicans* that remains susceptible to azoles, and should be treated for 14 days with oral azoles. Some nonalbicans *Candida* will respond to itraconazole or boric acid gelatin capsules (600 mg daily for 14 days) intravaginally. Treatment of sex partners is not recommended, but may be considered for females who have recurrent infection.

**GENITAL ULCERATIONS**

In the United States, young, sexually active patients who have genital ulcers have genital herpes or syphilis. The relative frequency of each disease differs by geographic area and patient population; however, in most areas, genital herpes is the most prevalent of these diseases. More than one of these diseases could be present in a patient with genital ulcers. All ulcerative diseases are associated with an increased risk for HIV infection. Oral and genital lesions may be presenting symptoms during primary HIV infection (acute retroviral syndrome). Less common causes of genital ulceration include chancroid and donovanosis.

Location of the ulcers is dependent on the specific type of sexual behavior. Ulcers may be vaginal, vulvar, cervical, penile, or rectal. Oral lesions may occur concomitantly with genital ulcerations or as stand-alone lesions in HSV infection and syphilis. Each etiologic agent has specific characteristics that are described in the following sections. Lesion pain, inguinal lymphadenopathy, and urethritis may be found in association with the ulcers.

1. **Herpes Simplex Virus Infection**

*(See Also Chapter 40)*

**General Considerations**

HSV is the most common cause of visible genital ulcers. HSV-1 and HSV-2 are viruses that infect primarily humans. HSV-1 is commonly associated with infections of the face, including the eyes, pharynx, and mouth. HSV-2 is most commonly associated with anogenital infections. However, each serotype is capable of infecting either region. HSV-1 infections are frequently established in children by age 5; lower socioeconomic groups have higher infection rates. Both HSV-1 and HSV-2 are STIs. The prevalence of both infections in the United States increases during teen years. Rates of HSV-2 seroprevalence reach 20%–40% in 40-year-olds. HSV infections are chronic as a result of latent infection of sensory ganglia. Latent infection is life long, although many individuals infected with HSV-2 infections have not been diagnosed or have had mild or unrecognized symptoms. Nevertheless, these individuals can still asymptotically shed virus and thereby unknowingly transmit the infection, and they can reactivate the virus to cause clinical infection in themselves.
Clinical Findings

A. Symptoms and Signs

Symptomatic initial genital HSV infection causes vesicles of the vulva, vagina, cervix, penis, rectum, or urethra, which are quickly followed by shallow, painful ulcerations. Atypical presentation of HSV infection includes vulvar erythema and fissures. Urethritis may occur. Initial infection can be severe, lasting up to 3 weeks, and be associated with fever and malaise, as well as localized tender adenopathy. The pain and dysuria can be extremely uncomfortable, requiring sitz baths, topical anesthetics, and occasionally catheterization for urinary retention.

Symptoms tend to be more severe in females. Recurrence in the genital area with HSV-2 is likely (65%–90%). Approximately 40% of individuals infected with HSV-2 will experience more than or equal to six recurrences per year in the early years after initial infection. Prodromal pain in the genital, buttck, or pelvic region is common prior to recurrences. Recurrent genital herpes is of shorter duration (5–7 days), with fewer lesions and usually no systemic symptoms. Commonly, there is decreased frequency and severity of recurrences over time, although approximately one-third of individuals fail to demonstrate this time-dependent improvement. First-episode genital herpes infection caused by HSV-1 is usually the consequence of oral-genital sex. Primary HSV-1 infection is as severe as HSV-2 infection, and treatment is the same. Recurrence of HSV-1 happens in less than 50% of patients, and the frequency of recurrences is much less than in those patients with prior HSV-2 infection.

B. Laboratory Findings

Diagnosis of genital HSV infection is often made presumptively, but in one large series this diagnosis was incorrect for 20% of cases. Several laboratory tests can aid in confirmation of the diagnosis. Viral culture has been the gold standard and can provide results in as few as 48 hours. Culture must be obtained by unroofing an active vesicle and swabbing the base of the lesion. DFA testing can provide results within hours. DFA can also determine serotype, which is important for prognosis. NAAT of viral DNA is becoming a more common diagnostic method.

Differential Diagnosis

Genital HSV infections must be distinguished from other ulcerative STI lesions, including syphilis, chancroid, and lymphogranuloma venereum. Non-STIs might include herpes zoster, Behçet syndrome, or lichen sclerosis. (See next sections on Syphilis and Chancroid.)

Complications

Complications, almost always with the first episode of genital HSV infection, include viral meningitis, urinary retention, transmission to newborns at birth, and pharyngitis. Infection with genital HSV, whether active or not, greatly increases the likelihood of transmitting or acquiring HIV infection within couples discordant for HIV.

Prevention

All patients with active lesions should be counseled to abstain from sexual contact. Almost all patients have very frequent periodic asymptomatic shedding of HSV, and most cases of genital HSV infection are transmitted by persons who are unaware that they have the infection or are asymptomatic when transmission occurs. Reactivation with asymptomatic shedding occurs even in individuals who were asymptotically infected. Individuals with prior HSV infection should be encouraged to use condoms to protect susceptible partners. Antiviral prophylaxis of infected individuals reduces shedding and significantly reduces the chance of transmission to their sexual partners.

Treatment

Antiviral drugs administered within the first 5 days of primary infection decrease the duration and severity of HSV infection (see Table 44–1). The effect of antivirals on the severity or duration of recurrent disease is limited. For best results, therapy should be started with the prodrome or during the first day of the attack. Patients should have a prescription at home to initiate treatment. If recurrences are frequent and cause significant physical or emotional discomfort, patients may elect to take antiviral prophylaxis on a daily basis to reduce the frequency (70%–80% decrease) and duration of recurrences. Treatment of first or subsequent attacks will not prevent future attacks, but recurrence frequency and severity decrease in many individuals over time.

2. Syphilis

General Considerations

Syphilis is an acute and chronic STI caused by infection with Treponema pallidum. The national rate of syphilis has increased annually since reaching an all time low in 2000. Increases have been observed in both genders, but predominantly in males who have sex with men, who now account for 72% of primary and secondary cases reported to
the CDC. In 2011, the CDC reported over 13,970 new cases of primary and secondary syphilis. Men between the ages of 15–24 years have the highest rates of syphilis; 4 out of 10 people with syphilis are also infected with HIV.

### Clinical Findings

#### A. Symptoms and Signs

Skin and mucous membrane lesions characterize the acute phase of primary and secondary syphilis. Lesions of the bone, viscera, aorta, and central nervous system predominate in the chronic phase (tertiary syphilis) (see Chapter 42). Prevention of syphilis is also important because syphilitic mucosal lesions facilitate transmission of HIV.

Primary syphilis usually presents as a solitary chancre at the point of inoculation. Characteristically, the chancre presents as a painless, indurated, nonpurulent ulcer with a clean base and associated nontender, firm adenopathy. The chancre appears on average 21 days (range: 3–90 days) after exposure and resolves spontaneously 4–8 weeks later. Because it is painless, it may go undetected, especially if the lesion is within the vagina, oropharynx, urethra, or rectum. Chancre may occur on the genitalia, anus, or oropharynx. Secondary syphilis occurs 4–10 weeks after the chancre appears, with generalized malaise, adenopathy, and a nonpruritic maculopapular rash that often includes the palms and soles. Secondary syphilis resolves in 1–3 months, but can recur. Verrucous lesions known as condylomata lata may develop on the genitalia. These must be distinguished from genital warts.

#### B. Laboratory Findings

If a patient has a suspect primary lesion, is at high risk, is a contact, or may have secondary syphilis, a nontreponemal serum screen—either RPR or VDRL—should be performed. If the nontreponemal test is positive, then a specific treponemal test—a fluorescent treponemal antibody-absorbed (FTAABS) or microhemagglutination–T pallidum (MHA-TP) test—is done to confirm the diagnosis. An additional diagnostic tool is darkfield microscopy, which can be used to detect spirochetes in scrapings of the chancre base. Darkfield examinations and DFA tests of lesion exudate or tissue are the definitive methods for diagnosing early syphilis.

If a patient is engaging in high-risk sexual behavior or is living in an area in which syphilis is endemic, RPRs should be drawn yearly to screen for asymptomatic infection. Annual RPR testing among high-risk groups is essential to distinguish between early latent syphilis (1 year or less postinfection), late latent syphilis (> 1 year postinfection), or syphilis of unknown duration, as treatment recommendations vary. Syphilis is reportable to state health departments, and all sexual contacts need to be evaluated. Patients also need to be evaluated for other STIs, especially HIV. HIV-infected patients have increased rates of failure with some treatment regimens and treatment of the HIV infection should occur as soon as indicated after diagnosis.

### Complications

Untreated syphilis can lead to tertiary complications with serious multiorgan involvement, including aortitis and neurosyphilis. Transmission to the fetus can occur from an untreated pregnant individual (see Chapters 2 and 42).

### Treatment

See Table 44–1 for treatment recommendations. Patients should be reexamined and serologically evaluated with nontreponemal tests at 6 and 12 months after treatment. If signs or symptoms persist or recur, or patients do not have a fourfold decrease in their nontreponemal test titer, they should be considered to have failed treatment or be reinfected and need retreatment.

### 3. Chancroid

#### General Considerations

Chancroid is caused by Haemophilus ducreyi. It is relatively rare outside of the tropics and subtropics, but is endemic in some urban areas in the United States, and has been associated with HIV infection, drug use, and prostitution. A detailed history, including travel, may prove to be important in identifying this infection.

#### Clinical Findings

##### A. Symptoms and Signs

The typical lesion begins as a papule that erodes after 24–48 hours into an ulcer. The ulcer is painful and has ragged, sharply demarcated edges and a purulent base (unlike syphilis). The ulcer is typically solitary and somewhat deeper than HSV infection. The lesions may occur anywhere on the genitals and are more common in men than in women. Tender, fluctuant (unlike syphilis and HSV) inguinal adenopathy is present in 50% of patients. A painful ulcer in combination with suppurative inguinal adenopathy is very often chancroid.
B. Laboratory Findings

Gram stain shows gram-positive cocci arranged in a boxcar formation. Culture, which has a sensitivity of less than 80%, can be performed on a special medium that is available in academic centers. NAAT testing may improve laboratory diagnosis in areas where such testing is available.

Differential Diagnosis

Chancroid is distinguished from syphilis by the painful nature of the ulcer and the associated tender suppurative adenopathy. HSV vesicles often produce painful ulcers, but these are multiple, smaller, and shallower than chancroid ulcers. Adenopathy associated with initial HSV infection does not suppurate. A presumptive diagnosis of chancroid should be considered in a patient with typical painful genital ulcers and regional adenopathy when the test results for syphilis and HSV are negative.

Treatment

Symptoms improve within 3 days after therapy (see Table 44–1). Most ulcers resolve in 7 days, although large ulcers may take 2 weeks to heal. All sexual contacts need to be examined and given treatment, even if asymptomatic. Individuals with HIV coinfection may have slower rates of healing or treatment failures.

4. Lymphogranuloma Venereum

General Considerations

Lymphogranuloma venereum (LGV), caused by C trachomatis serovars L1, L2, or L3, is generally rare in the United States. The disease is endemic in Southeast Asia, the Caribbean, Latin America, and areas of Africa. Since 2003, an increased number of cases in the United States, Western Europe, and Canada have occurred primarily among men who have sex with men and have been associated with HIV coinfection.

Clinical Findings

A. Symptoms and Signs

Patients with LGV present with a painless vesicle or ulcer that heals spontaneously, followed by development of tender adenopathy, either unilateral or bilateral. A classic finding is the groove sign—an inguinal crease created by concomitant involvement of inguinal and femoral nodes. These nodes become matted and fluctuant and may rupture. LGV can cause proctocolitis with rectal ulceration, purulent anal discharge, fever, tenesmus, and lower abdominal pain, primarily in men who have sex with men.

B. Laboratory Findings

Diagnosis of LGV can be difficult. It generally requires a clinical suspicion based on physical examination findings. Lesion swabs and lymph node aspirates can be tested for Chlamydia by culture, DFA, or NAAT. NAAT is not FDA cleared for rectal specimens. Additional genotyping is necessary to differentiate LGV from non-LGV serovars of Chlamydia. In the absence of laboratory testing to confirm the diagnosis, one should treat for LGV if clinical suspicion is high.

Differential Diagnosis

Differential diagnosis during the adenopathy phase includes bacterial adenitis, lymphoma, and cat-scratch disease. Differential diagnosis during the ulcerative phase encompasses all causes of genital ulcers.

Treatment

See Table 44–1 for treatment recommendations. Despite effectiveness of azithromycin for non-LGV chlamydial infections, there have been no controlled treatment trials to recommend its use in LGV. HIV-infected individuals are treated the same as non-HIV infected individuals, but should be monitored closely to assess response to treatment.

5. Other Ulcerations

Granuloma inguinale, or donovanosis, is caused by Klebsiella granulomatis, a gram-negative bacillus that is rare in the United States, but is endemic in India, the Caribbean, and southern Africa. An indurated subcutaneous nodule erodes to form a painless, friable ulcer with granulation tissue. Diagnosis is based on clinical suspicion and supported by a Wright or Giemsa stain of the granulation tissue that reveals intracytoplasmic rods (Donovan bodies) in mononuclear cells. See Table 44–1 for treatment recommendations. Relapse may occur 6–18 months after apparently effective treatment with a 3-week course of doxycycline.
GENITAL WARTS & HUMAN PAPILLOMAVIRUS

General Considerations

Condylomata acuminata, or genital warts, are caused by HPV, which can also cause cervical dysplasia and cervical cancer. HPV is transmitted sexually. An estimated 20 million people in the United States are infected annually with HPV, including approximately more than 9 million sexually active adolescents and young adults 15–24 years of age. The majority (74%) of new HPV infections occurs among those 15–24 years of age; in females younger than age 25 years, the prevalence ranges between 28% and 46%. It is estimated that 32%–50% of adolescent females having sexual intercourse in the United States have HPV infections, though only 1% may have visible lesions. Thirty to 60% of males whose partners have HPV have evidence of condylomata on examination. An estimated 1 million new cases of genital warts occur every year in the United States.

Although there are almost 100 serotypes of HPV, types 6 and 11 cause approximately 90% of genital warts, and HPV types 16 and 18 cause more than 70% of cervical dysplasia and cervical cancer. The infection is more common in persons with multiple partners and in those who initiate sexual intercourse at an early age.

Pap smears should be obtained starting at age 21 and then every 3 years. More frequent and earlier evaluations are recommended if there are additional risk factors such as coinfection with HIV.

Clinical Findings

A. Symptoms and Signs

For males, verrucous lesions are found on the shaft or corona of the penis. Lesions also may develop in the urethra or rectum. Lesions do not produce discomfort. They may be single or found in clusters. Females develop verrucous lesions on any genital mucosal surface, either internally or externally, and often develop perianal lesions.

B. Laboratory Findings

External, visible lesions have unique characteristics that make the diagnosis straightforward. Condylomata acuminata can be distinguished from condylomata lata (syphilis), skin tags, and molluscum contagiosum by application of 5% acetic acid solution. Acetowhiteness is used to indicate the skin tags, and molluscum contagiosum by application of 5% acetic acid solution. Acetowhiteness is used to indicate the skin tags, and molluscum contagiosum by application of 5% acetic acid solution. It is recommended for females and males aged 9–26 years. Males are protected against genital warts, and anal cancer, which has a significantly increased incidence in males who practice anal sex. The bivalent HPV vaccine is greater than 93% effective in preventing HPV-16 and 18–related cervical dysplasia, but cervical cells. These changes range from atypical squamous cells of undetermined significance (ASCUS) to low-grade squamous intraepithelial lesions (LSIL) and high-grade squamous intraepithelial lesions (HSIL). LSIL encompasses cellular changes associated with HPV and mild dysplasia. HSIL includes moderate dysplasia, severe dysplasia, and carcinoma in situ.

Follow-up for ASCUS is controversial, as only 25% progress to dysplasia, and the remainder are stable or regress. Updated recommendations prefer repeat cytology in 12 months with no HPV DNA testing. If a test for HPV DNA is performed and is positive, then repeat cytology in 12 months is recommended. If the grade of the atypical squamous cells remains uncertain or if there is HSIL, colposcopy is recommended. If LSIL is detected, colposcopy is not needed, but a repeat Pap smear should be done in 1 year, and if LSIL or HSIL are subsequently detected, the patient should be referred for colposcopy for direct visualization or biopsy of the cervix (or both). If a Pap smear shows signs of inflammation only, and concomitant infection such as vaginitis or cervicitis is present, the smear should be repeated after the inflammation has cleared.

Differential Diagnosis

The differential diagnosis includes normal anatomic structures (pearly penile papules, vestibular papillae, and sebaceous glands), molluscum contagiosum, seborrheic keratosis, and syphilis.

Complications

Because genital warts can proliferate and become friable during pregnancy, many experts advocate their removal during pregnancy. HPV types 6 and 11 can cause laryngeal papillomatosis in infants and children. Complications of appropriate treatment include scarring with changes in skin pigmentation or pain at the treatment site. Pap smears with persistent or high-grade dysplasia require biopsy and/or resection, which may result in cervical abnormalities that complicate pregnancy. Cervical cancer is the most common and important sequelae of HPV.

Prevention

The use of condoms significantly reduces, but does not eliminate, the risk for transmission to uninfected partners. The quadrivalent HPV vaccine is 96%–100% effective in preventing HPV-6 and 11–related genital warts and HPV-16 and 18–related cervical dysplasia. It is recommended for females and males aged 9–26 years. Males are protected against genital warts, and anal cancer, which has a significantly increased incidence in males who practice anal sex. The bivalent HPV vaccine is greater than 93% effective in preventing HPV-16 and 18–related cervical dysplasia, but...
has no effect on genital warts. It is recommended only for girls aged 10–25 years (see Chapter 10).

**Treatment**

Penile and external vaginal or vulvar lesions can be treated topically. Treatment may need to occur weekly for 4–6 weeks. An experienced practitioner should treat internal and cervical lesions (see Table 44–1). Treatment may clear the visible lesions, but not reduce the presence of virus, nor is it clear whether transmission of HPV is reduced by treatment.

Warts may resolve or remain unchanged if left untreated or they may increase in size or number. Treatment can induce wart-free periods in most patients. Most recurrences occur within the 3 months following completion of a treatment regimen. Appropriate follow-up of abnormal Pap smears is essential to detect any progression to malignancy.

**OTHER VIRAL INFECTIONS**

1. **Hepatitis (See Also Chapter 22)**

   **General Considerations**

   In the United States, viral hepatitis is linked primarily to three viruses: hepatitis A (HAV), hepatitis B (HBV), and hepatitis C (HCV). Each virus has the potential to be spread through sexual activity. HAV is spread via fecal-oral transmission and oral-anal contact. Both HBV and HCV are spread through contact with blood or body fluids. Sexual transmission of HBV is believed to be much more efficient than that of HCV although recent data has suggested increased transmission of HCV in MSM.

   Universal immunization recommendations for HAV and HBV have contributed to the decline in prevalence of these diseases. However, individuals born before implementation of routine vaccination, especially those in high-risk groups (multiple sexual partners or men who have sex with men), should receive vaccination.

2. **Human Immunodeficiency Virus (See Also Chapter 41)**

   **General Considerations**

   In 2009, 39% of new HIV infections in the United States occurred in youth and young adults aged 13–29 years. Data suggest that adolescents and young adults are less likely to be aware of their HIV infection than older individuals with HIV. Because of the long latency period between infection with HIV and progression to AIDS, it is felt that many HIV-positive young adults contracted HIV during adolescence. CDC incidence data indicate that young men who have sex with men continue to be the highest-risk group, particularly young men of color. Young women account for approximately one-third of the infections in this age group with black and Hispanic women bearing a disproportionate burden of the disease. Risk factors for contracting HIV include a prior STI, infrequent condom use, practicing insertive or receptive anal sex (both males and females), prior genital HSV infection, practicing survival sex (ie, trading sex for money or drugs), intravenous drug or crack cocaine or crystal methamphetamine use, homelessness, and being the victim of sexual abuse (males).

   HIV infection should be considered in all sexually active youth, whether they have sex with males, females, or both. The CDC recommends that all sexually active individuals older than 13 be offered HIV testing at least once. Individual risk factors should then be used to determine the frequency of repeat testing. Opportunities for HIV screening in adolescents should include STI screening or treatment, pregnancy testing, or routine health evaluations. Most states allow adolescents to consent to HIV testing and treatment, but providers should be aware of their particular State’s laws.

   **Clinical Findings**

   **A. Symptoms and Signs**

   Adolescents may be asymptomatic with recent HIV infection or may present with the acute retroviral syndrome, which is evident 2–6 weeks after exposure. The acute clinical syndrome, which occurs in about 50% of patients, is generally indistinguishable from other viral illnesses with respect to fever, malaise, and upper respiratory symptoms. Distinguishing features include generalized lymphadenopathy, rash, oral and genital ulcerations, aseptic meningitis, and thrush. After the acute illness, signs and symptoms may be absent for many years.
B. Laboratory Findings

If acute HIV infection is suspected, HIV testing should be done by HIV RNA PCR testing or HIV DNA PCR testing. Routine serological testing may not be positive for 6 weeks or longer. Viral load values of less than 10,000 copies/mL by RNA PCR may indicate a false positive in this setting and repeat testing would be indicated.

Routine HIV screening may be conducted either by blood or by oral fluids. The testing relies on ELISA screening; a positive ELISA test must be confirmed by Western Blot testing. These methods have high degrees of sensitivity and specificity, but positive predictive values rely on underlying prevalence in individual communities.

Treatment

The most important aspect of identifying adolescents and young adults with HIV infection is linking them to care. Data support the treatment of youth with HIV infection in care settings that provide comprehensive, multidisciplinary care. These settings will be best equipped to provide emotional support, preventative care, risk reduction for contacts, access to research, and guidance on the appropriate timing of antiretroviral therapies.

3. HIV Postsexual Exposure Prophylaxis

Adolescents may present to healthcare providers seeking postexposure prophylaxis (nPEP) following an assault or a high-risk sexual encounter. The risk of acquiring HIV infection through sexual assault or abuse is low but present. The risk for HIV transmission from a positive contact per episode of receptive penile-anal sexual exposure is estimated at 0.5%–3%; the risk per episode of receptive vaginal exposure is estimated at less than 0.1%–0.2%. HIV transmission also occurs from receptive oral exposure, but the risk is unknown. The risk of HIV transmission may be increased in certain conditions: trauma, including bleeding, with vaginal, anal, or oral penetration; site of exposure to ejaculate; HIV viral load in ejaculate; duration of HIV infection in the assaulter or partner; and presence of an STI, prior genital HSV infection, or genital lesions in either partner. The risk is greatly reduced if the contact is successfully receiving antiretroviral therapy.

Healthcare providers that consider offering PEP should take into account the likelihood that exposure to HIV occurred, the potential benefits and risks of such therapy, and the interval between the exposure and initiation of therapy. It will be helpful to know the HIV status of the sexual contact. The CDC provides an algorithm for consideration of PEP. In general, PEP is not recommended when more than 72 hours have passed since exposure. If the patient decides to take PEP, clinical management should be implemented according to published CDC guidelines. Providers should be aware that structural barriers exist to obtaining PEP, and that adolescent assault victims have a high discontinuation rate due to adverse effects from the medication.

4. HIV Preexposure Prophylaxis (PrEP)

In July 2012, the CDC issued interim guidance on the use of PrEP in adult heterosexual couples; interim guidance on its use in adult MSM was released in 2011. The guidance followed the Food and Drug Administration’s approval of a co-formulated HIV antiretroviral (tenofovir and emtricitabine) for use as preexposure prophylaxis based on data from two large international trials. The approval for use does not include individuals under age 18 years. Further research is being conducted to determine safety and acceptability in younger individuals at high risk for HIV acquisition. Providers considering the use of PrEP in a minor at risk of infection would be advised to consult with an experienced prescriber and know the laws of their particular state with respect to providing preventive HIV medication without parental consent.
ECTOPARASITIC INFECTIONS

1. Pubic Lice

*Pthirus pubis*, the pubic louse, lives in pubic hair. The louse or the nits can be transmitted by close contact from person to person. Patients complain of itching and may report having seen the insect. Examination of the pubic hair may reveal the louse crawling around or attached to the hair. Closer inspection may reveal the nit or sac of eggs, which is a gelatinous material (1–2 mm) stuck to the hair shaft. See Table 44–1 for treatment recommendations.

2. Scabies

*Sarcoptes scabiei*, the causative organism in scabies, is smaller than the louse. It can be identified by the classic burrow, which is created by the organism laying eggs and traveling just below the skin surface. Scabies can be sexually transmitted by close skin-to-skin contact and can be found in the pubic region, groin, lower abdomen, or upper thighs. The rash is intensely pruritic, especially at night, erythematous, and scaly. See Table 44–1 for treatment options. Ivermectin is an oral therapeutic option for scabies that may hold particular promise in the treatment of severe infestations or in epidemic situations. When treating with lotion or shampoo, the entire area needs to be covered for the time specified by the manufacturer. One treatment usually clears the infestation, although a second treatment may be necessary. Bed sheets and clothes must be washed in hot water. Both sexual and close personal or household contacts within the preceding month should be examined and treated.

REFERENCES

INTRODUCTION
Twenty-seven million people from the United States travel internationally per year; one-third of them travel to developing nations. Fifty to 70% of travelers become ill during their travel overseas. The number of children traveling with families continues to increase. Children are usually more susceptible to infectious diseases, trauma, and other health problems, which vary with the destination. Preparation for travel with children and infants includes consideration of the destination-specific risks, underlying medical problems, and administration of both routine and travel-related vaccines. The physician involved in pretravel counseling should focus on the issues listed in Table 45–1.

PREPARING CHILDREN AND INFANTS FOR TRAVEL

Travel Plans
Parents and care providers should be advised that travel with children and infants is much more enjoyable when the number of journeys in a single trip is limited; travel time is kept relatively short; and travel delays are anticipated. Planning for delays and other problems should include bringing new or favorite toys or games for distraction, and carrying extra food and drink, changes of clothing, and fever medications.

Medical Care During Travel
It is useful to obtain the names and addresses of local health care providers at the family’s destination. This is available from travel medicine practitioners or from the membership directory of the International Society of Travel Medicine. The International Association for Medical Assistance to Travelers website (www.iamat.org) is another useful resource with a worldwide directory of providers proficient in English. Travel insurance is highly encouraged. Insurance providers not only cover medical care at the destination, but provide 24-hour help lines with information regarding English-speaking physicians and hospitals, and can arrange and pay for evacuation to a medical facility that provides necessary treatment if not available locally. In emergencies, parents and caretakers should take their children to the largest medical facility in the area, which is more likely to have a pediatric unit and trauma services.

Trauma
Trauma is the most common cause of morbidity and mortality in traveling children. Parents should rent larger, safer vehicles, and use car seats whenever possible. However, in many developing countries, car seats are not available, so caretakers may need to travel with their own. Taxis often do not have seatbelts, so it may be necessary to request taxis with seatbelts by calling in advance.

Air Travel
Healthy term infants can travel by commercial pressurized airplane. Children at higher risk during air travel may include premature infants and those with chronic cardiac or pulmonary disease, so appropriate counseling with their specialist is indicated. Many parents request advice regarding sedation of their child during travel. While this is not recommended, the most widely used agent is diphenhydramine. It is advisable to try a test dose prior to travel as idiosyncratic reactions, and overdosing can lead to an anticholinergic syndrome or a paradoxical stimulating effect.

Ear Pain
Children and infants often have pain during ascent and descent of commercial airplanes due to changes in middle ear pressure causing retraction or protrusion of the tympanic membrane. Methods said to alleviate or minimize ear pain
during these times include chewing, swallowing, nursing, and bottle feeding.

**Motion Sickness**

Almost 60% of children will experience motion sickness during travel. While older children have symptoms similar to those in adults (such as nausea, epigastric discomfort, headache, general discomfort), children younger than 5 years may have gait abnormalities as the predominant symptom. Nonpharmacologic strategies include eating a light meal at least 3 hours before travel; avoiding dairy products and foods high in calories, protein, and sodium before travel; sitting in the middle of the back seat or in the front seat if age-appropriate; focusing on a stable object or the horizon; avoiding reading or other visual stimuli; eye closure; fresh air; and limiting excessive head movement. Pharmacologic intervention has not been well studied in children, but if necessary, antihistamines such as diphenhydramine is recommended for children younger than 12 and scopolamine is acceptable for children older than 12 years. These measures, however, are not evidence-based.

**High Altitude**

Acute mountain sickness is as common in children as in adults, but it may go unrecognized due to its subtle presentation, such as unexplained fussiness or change in appetite and sleep patterns. High-altitude pulmonary edema (HAPE) is seen in children traveling to high altitudes; it also occurs in children who live at high altitude, descend for an extended period, and return to altitude. Mild symptoms of altitude sickness can be treated with rest and hydration, or analgesics such as ibuprofen or acetaminophen. High-altitude sickness is milder and resolves much more quickly in children compared to adults, so prophylaxis is usually not required. Acetazolamide has not been studied in children for acute mountain sickness, but it is safe in this age group and has been used for both prophylaxis and treatment. The pediatric dose is 5 mg/kg/d (125 mg maximum) divided twice daily, starting 1 day before ascent, and continued for 2 days at high altitude.

**Medications/First-Aid Kit**

A small medical kit is useful when traveling. Included in this kit should be medications for illnesses that the child experiences at home, trip-specific items, and the usual first-aid kit items (Table 45–2). Medications should be purchased prior to travel, as those obtained at some destinations may be of poor quality or contain toxic substances.

**Table 45–1. Preparing for travel—issues specific to travel as indicated.**

| Vaccinations (indications, safety, and tolerability) |

VACCINATIONS—ROUTINE CHILDHOOD VACCINES MODIFIED FOR TRAVEL

Many vaccine-preventable diseases remain prevalent in developing countries, and outbreaks still occur in areas where these diseases are considered rare. The schedule for some vaccines may be accelerated for travel, and some vaccines can be given earlier than the recommended age. Vaccination pertaining to children traveling follows the routine vaccination schedule as outlined in Chapter 10. The recommended intervals balance the high-risk age for disease with infant immunologic responses. The recommended minimum interval between doses is listed in Table 45–3. Barriers to some early immunizations are antibody from the mother interfering with an infant’s ability to mount an antibody response, particularly to live vaccines, and the lack of a T-cell–dependent immune response to certain immunogens in those younger than 2 years. For children traveling to highly endemic areas, however, it is preferable to vaccinate prior to the recommended age despite the possible need for repeat vaccination at a later date. Minor febrile illnesses are not a contraindication to routine or travel vaccines and should not lead to their postponement. Live vaccines should be given together or separated by 30 days or more.

**Diphtheria-Tetanus-Acellular Pertussis Vaccine**

Immunization is recommended prior to travel to developing countries because of the greater risk of disease from diphtheria, tetanus, and pertussis. Tetanus risk is high in several areas of the developing world where fecal contamination of soil is extensive. Infants should receive their first diphtheria-tetanus-acellular pertussis (DTaP) at 6 weeks of age for an adequate immune response, with a 4-week interval between the subsequent two doses. Adequate protection is achieved after the third dose. The fourth dose may be given 6–12 months after the third dose provided that the child is 12 months of age or older. Tdap is licensed for children at least 11 years of age. Adolescents and adult caretakers, who are prominent vectors in the spread of pertussis to young children, should receive a single Tdap booster. If more than 5 years has elapsed since the last dose, a booster should be considered for children and adolescents to minimize tetanus risk. Tdap is preferred to Td in children older than 11 years if they have not received Tdap previously.

DTaP, diphtheria-tetanus-acellular pertussis; DTP, diphtheria-tetanus-pertussis; Hib, *Haemophilus influenzae* type b; IPV, inactivated polio vaccine; MCV, meningococcal conjugate vaccine; MMR, measles-mumps-rubella; MPS4, meningococcal polysaccharide; PCV, pneumococcal conjugate vaccine.

<sup>a</sup>Children traveling abroad may be vaccinated as early as 6 months of age. Before departure, children aged 6–11 months should receive the first dose of MMR vaccine. This will not count toward their series, and they will still require two doses after 12 months of age.

<sup>b</sup>The third dose should be given at least 4 months after the first dose and at a minimum of 6 months of age.

<sup>c</sup>If third dose is given after 4 years, the fourth dose is not required.

<sup>d</sup>Recommended at 6–18 months of age, minimum age 4 years for final dose.

<sup>e</sup>Minimum 6 weeks for Hib-MenCY, 9 months for Menactra (MCV4-D), 2 years for Menveo (MCV4-CRM). Repeat vaccination depends on host status and ongoing risk factors.

<sup>f</sup>This differs from the package insert but is validated by data held by the manufacturer.
Haemophilus influenzae Type b Vaccine

The indications for vaccination of *Haemophilus influenzae* type b (Hib) in children traveling are the same as for the US residents. If previously unvaccinated, infants younger than 15 months should receive at least two doses prior to travel. An accelerated schedule can start at a minimum of 6 weeks of age, with a 4-week interval between the first, second, and third doses, and at least 8 weeks between third and fourth doses.

Hepatitis A Vaccine

Hepatitis A is one of the most common vaccine-preventable illnesses globally, and vaccination should be provided prior to travel to developing countries. In many developing countries, more than 90% of local children have hepatitis A antibodies by 6 years of age. The disease is much less common in children from the developed world, so they are likely to be susceptible when traveling to high-risk areas. Although two doses of the vaccine are recommended 6–12 months apart, a single dose will provide protection during the trip if given at least 2 weeks prior to departure. The earliest age of administration is 1 year in the United States. Immune globulin for hepatitis A (0.02 mL/kg IM) can be given for protection of children younger than 1 year, or if travel will occur within 2 weeks after vaccination. This interferes with MMR and varicella vaccination, so these vaccines should be given 2 weeks prior to immunoglobulin.

Hepatitis B Vaccine

Areas of high endemicity for hepatitis B include most of Asia, the Middle East, Africa, and the Amazon Basin. Unimmunized children are at risk if they receive blood transfusions that have not been screened for HBV surface antigen (HBsAg) or are exposed to unsterilized medical or dental equipment. Children traveling to developing countries should be vaccinated before departure. An accelerated schedule is possible, with the second dose given with a minimum 4-week interval, and the third dose given at least 8 weeks after the second dose. The third dose should not be given before 24 weeks of age.

Influenza Vaccine

Children are at high risk of respiratory infection during travel. The influenza vaccine is recommended for travel during the influenza season, which is between September and March in the Northern Hemisphere, and between April and August in the Southern Hemisphere, and year round in the tropics. The vaccine available in the United States may not protect against new strains circulating in the Southern Hemisphere. Influenza vaccine is recommended for children at least 6 months of age; those younger than 9 years will need two doses of vaccine administered at least 4 weeks apart if they have never previously received the vaccine containing the 2009 H1N1 antigen contained in all influenza vaccines 2010–2011 and beyond. The current vaccines available are: the trivalent or quadrivalent inactivated vaccine (IIV) given intramuscularly, and the quadrivalent live attenuated vaccine (LAIV) given intranasally. It is preferable to be vaccinated at least 2 weeks prior to departure. The annual seasonal influenza vaccine may not be routinely available in the United States from the late spring to early fall, when it may be needed for travelers but may be available at some travel clinics. Revaccination is not recommended for those who will be traveling during April through September and were vaccinated the preceding fall.

Measles-Mumps-Rubella (MMR) Vaccine

While measles is no longer endemic in the United States, it is still prevalent in many parts of the world, including Europe. Children as young as 6 months of age traveling outside the United States are recommended to receive the vaccine, but any doses given prior to 12 months do not count toward an adequate two-dose series, as maternal antibodies may interfere with the immune response. These infants will still require one dose of measles-mumps-rubella (MMR) at 12–15 months of age and a second dose at 4–6 years of age. The second dose is to protect those individuals (~5%) who did not respond the first time. If an accelerated schedule is required, two doses must be separated by minimum of 4 weeks.

Meningococcal Vaccine

The highest risk for meningococcal disease is for travelers to the meningitis belt of Africa (sub-Saharan region) especially during the dry season, and travelers on the Hajj or Umrah pilgrimage to Mecca. Notably meningococcal disease is decreasing in this region due to vaccination against type A. There are two meningococcal vaccines available. The conjugated quadrivalent (MCV4) vaccine is approved for use in persons aged 9–23 months (two doses 8 weeks apart) and 2–55 years (one dose). This vaccine is recommended for those who live or travel to areas with high rates of meningitis. It must be given at least 10 days before international travel. The quadrivalent meningococcal polysaccharide vaccine (MPSV4) is licensed for persons 2 years or older. Both types of vaccines protect against serotypes A, C, Y, and W-135. The duration of protection is 3 years in children and 5 years in adults, and boosters are indicated for ongoing exposure and at risk hosts. Hib-MenCY-TT is the approved vaccination for the age group 6 weeks to 9 months; as it does not provide protection against serotypes A or Y, a previously vaccinated infant reaching the age of 9 months and travelling to endemic areas should be revaccinated with MCV4. MPSV4 should be used for persons older than 56 years. Vaccination
can be considered in children younger than 9 months with risk factors and/or traveling to an endemic area. Meningococcal vaccination is required by the Saudi Arabian government for pilgrims undertaking the Hajj or Umra pilgrimage to Mecca and Medina, because of the international outbreak of Neisseria meningitidis A in 1987 and W-135 in 2000 and 2001. Further information concerning geographic areas recommended for meningococcal vaccination can be obtained from http://www.cdc.gov/travel.

Recently, a new combined Hib and N meningitidis serogroup C conjugate vaccine has been licensed down to 6 weeks of age, but this should not be used for children travelling to the meningitis belt or the Hajj, as serogroup A is the predominant organism in these regions.

**Pneumococcal Vaccine**

*Streptococcus pneumoniae* infection is prevalent worldwide, and children younger than 2 years have the highest rates of disease. The 13-valent pneumococcal conjugate vaccine (PCV 13) is recommended for routine use in children aged 5 years or younger. In addition, the pneumococcal polysaccharide (PPSV23) is recommended for children and adults aged 2 years or older who have certain underlying medical conditions, and for all adults aged 65 years or older. For children aged 5 years or younger who have completed the PCV 7 series, a single additional dose of PCV 13 is recommended. The minimal interval is 4 weeks between the first three doses, and 8 weeks between the third and fourth dose.

**Polio Vaccine**

Transmission of wild-type polio still occurs in regions of Asia and Africa, and vaccine-derived polio is transmitted in other regions. Adequate immunization with inactivated polio vaccine (IPV) should be administered prior to travel to developing countries. The minimum age of administration is 6 weeks of age for IPV. The recommended interval between the first and second dose is 4 weeks as well as between the second and third dose, and 4 weeks between subsequent doses. One additional lifetime dose (a fifth dose) of the IPV should be given to caretakers who are traveling to areas with recent circulating polio.

**Rotavirus Vaccine**

Rotavirus is the most common cause of severe gastroenteritis in infants and young children worldwide, and vaccination with the complete series is recommended prior to travel if age-appropriate. The minimum and maximum age for the first dose is 4 weeks and 14 weeks, 6 days respectively. There is insufficient data on the safety in older infants. The minimum interval between doses is 4 weeks.

**Japanese Encephalitis Vaccine**

Japanese encephalitis (JE) is caused by a flavivirus transmitted by the night-biting Culex mosquito. The risk of contracting severe JE is low, especially for travelers who will have a brief stay in an endemic area, as the infection rate in Culex mosquitoes is 3% or lower, and only 1 in 200 infections with JE leads to neuroinvasive disease. The symptoms of JE include seizures, paralysis, coma, and mental status changes; residual neurological damage occurs in 50% of those with clinical disease. The case fatality rate is 30% in those with severe disease. Most symptomatic cases occur in children younger than 10 years and in the elderly. The areas at risk include most of Asia, Eastern Russia, some areas of the Western Pacific, and the Torres Strait Islands of Australia. The peak season is between April and October, during and just after the rainy season. The JE vaccine reduces the risk for disease among those who will be in a high-risk setting, as determined by the destination, duration, and season of travel. The JE vaccine licensed and available for use in the United States is Ixiaro, an inactivated Vero cell culture-derived vaccine. It was approved in May 2013 for use in children aged 2 months through 16 years, in addition to travelers older than 16 years of age. Other inactivated and live attenuated JE vaccines are manufactured and used in other countries, but are not licensed for use in the United States.

**Rabies Vaccine**

Rabies is found worldwide and contracted through the bite or saliva-contaminated scratch of infected animals. In parts of Africa, Asia, and Central and South America, canine rabies is highly endemic (Rabanet—www.who.int/rabies/rabnet/en/—provides country-specific animal and human data), where 40% of rabies occurs in children younger than 14 years. This increased risk is because children are attracted to animals, are more likely to be bitten, and may not report minor encounters with animals. Most cases of rabies in travelers occur through the bite of an infected dog, cat, or

---

**References**

monkeys (particularly those that live near temples in parts of Asia). Bats, mongooses, and foxes are other animals that can transmit disease.

The rabies vaccine is recommended for travelers to areas in which rabies is endemic and for those who will have occupational or recreational exposure (such as cavers), especially if access to medical care will be limited when traveling. The risk of a bite from a potentially rabid animal is up to 2% for travelers to the developing world. There are three types of inactivated virus vaccine available, which are administered prior to exposure in three doses at days 0, 7, and 21 or 28. Vaccination prior to exposure may not be completely protective; further doses are required if a high-risk bite occurs. The minimum age of administration is 1 year, and duration of protection is 2 years. Malaria chemoprophylaxis with mefloquine or chloroquine should begin 1 month after completing the rabies vaccine series to avoid interference with the immune response.

The manufacturers are currently unable to supply the rabies vaccine for preexposure prophylaxis and it is currently only available from distributors with existing stocks. There is no limitation in the supply of rabies immunoglobulin or vaccine for postexposure prophylaxis.

It is important to counsel travelers about animal avoidance, thorough cleansing of a bite wound with irrigation for at least 5 minutes, and the need for previously vaccinated individuals to seek additional vaccination on days 0 and 3 if an exposure occurs.

In the event of a bite in a nonvaccinated individual, rabies immunoglobulin and four doses of vaccine at days 0, 3, 7, and 14 are required, ideally within 24–48 hours after contact.

Yellow Fever Vaccine

Yellow fever is a flavivirus transmitted by mosquitoes, found in urban and rural areas in sub-Saharan Africa and equatorial South America. Of those infected with the virus, 15% have moderate to severe infection. The licensed 17D strain live attenuated vaccine is highly effective. It must be administered 10 days before travel to an endemic region to allow for the development of protective antibodies. It is required by many countries for reentry after travel to an endemic area, and receipt of the vaccine should be documented in the International Certificate of Vaccination that became available in December 2007 (wwwnc.cdc.gov/travel/yellowbook provides an updated list of countries in which yellow fever vaccination is recommended). For this reason, it is only administered at certified clinics. The vaccine is given subcutaneously, and a booster is required every 10 years (but immunity may be lifelong after a single dose). The recommended minimum age of administration is 9 months, and vaccine should not be administered to at-risk infants younger than 6 months, because of the increased risk of encephalitis (0.5–4 per 1000 vaccinees). The risk of severe vaccine-related disease is also higher in adult caretakers older than 60 years.

The decision to immunize infants who are 6–8 months of age must balance the infant's risk for exposure with the risk for vaccine-associated encephalitis. The vaccine should not be administered to individuals with egg allergy or immunosuppression (including a history of thymus disorder or thymectomy). A letter of medical exemption may be required for these travelers. In addition to age limitations, precautions to vaccination include asymptomatic HIV infection and CD4 T-lymphocyte count of 200–499 cells/mm$^3$, pregnancy, and breast-feeding. Adverse effects include encephalitis (15 per million doses for those aged > 60 years) and multisystem disease (5 per million doses in older people).

Cholera Vaccine

The cholera vaccine is no longer produced in the United States and is no longer recommended for international travel, as the disease is rare in travelers. There are live and killed vaccines available in other countries, but these confer only slight protection.

Typhoid Vaccine

The risk of typhoid fever in travelers is 1–10:100,000, depending on the destination. Areas at risk include South Asia, West and North Africa, South America, and Latin America. Travelers to the Indian subcontinent are at greatest risk.

The vaccine is recommended for long-term travelers traveling to an endemic area, those traveling off standard tourist routes, immunocompromised travelers, those of south Indian ancestry, and patients with cholecystitis. There are two vaccines available: a capsular polysaccharide (ViCPS) and a live attenuated (Ty21a) vaccine. The ViCPS is given intramuscularly 2 weeks prior to travel. The minimum age of administration for this vaccine is 2 years; efficacy is 75% over 2 years. The Ty21a is an oral vaccine given as four doses every second day, which needs to be completed more than 1 week prior to travel to be effective. It is licensed for children older than 6 years; efficacy is 80% over 5 years. It is contraindicated in immunodeficient populations. Antibiotics interfere with growth of the vaccine strain bacteria. Mefloquine, chloroquine, and prophylactic doses of atovaquone-proguanil can be given concurrently with the typhoid vaccine. Fever, headache, and severe local pain and swelling are reported with the ViCPS more frequently than with other vaccines. A recent recall of some lots of the ViCPS vaccine (because of low antigen content) may lead to some vaccine shortages.

Tuberculosis

Tuberculosis risk is increased for travelers, especially when visiting Africa, Asia, Latin America, and the former Soviet Union. The risk is higher in long-term travelers to countries with a high incidence of tuberculosis and is highest among health care workers. Bacillus Calmette-Guérin (BCG) vaccination is
Traveler’s Diarrhea

Diarrhea is one of the most common illnesses in travelers to the developing world. Children are at highest risk, usually having more severe and prolonged illness than adults. Traveler’s diarrhea is defined in adults as three or more loose stools in a 24-hour period, plus either fever, nausea, vomiting, or abdominal cramping. There is no strict definition in child travelers, as the pattern, consistency, and frequency of stools vary during the course of childhood. A useful definition to use for traveling children is a recent change in normal stool patterns, with an increase in frequency (at least three stools per 24 hours) and a decrease in consistency to an unformed state. Most illnesses usually resolve over a 3- to 5-day period and occur in the first 2 weeks of travel. Enterotoxigenic *Escherichia coli* (ETEC) is the most common cause, accounting for up to one-third of cases. Other pathogens implicated are listed in Table 45-4. Counseling prior to travel includes education and caution with food handling and food and water consumption, and provision for self-treatment in the event of illness.

Prevention

Travelers should be advised to seek restaurants with a good safety reputation; to eat hot, thoroughly cooked food; to eat fruits and vegetables that can be peeled by the traveler; and to avoid tap water. They should also avoid ice cubes, fruit juices, fresh salads, unpasteurized dairy products, cold sauces and toppings, open buffets, undercooked foods, and food or beverages from street vendors. They should check the integrity of caps before buying bottled water to avoid bottles filled with tap water. It is also useful to remind the travelers about hand washing after using the toilet and before eating. Families can consider using alcohol-containing hand sanitizers as an alternative to soap and water when access is limited during travel. Pasteurized or boiled milk is considered safe provided that it is stored at the appropriate temperature. It may be necessary to bring powdered milk to mix it with safe drinking water if the quality of milk is questionable. While these measures seem logical and should be recommended, there is little evidence that they prevent traveler’s diarrhea, either in adults or in children.

Chemoprophylaxis & Treatment

The principles of treatment include adequate hydration and a short course of antibiotics when warranted; medical attention should be sought for severe or prolonged disease.

---
For mild disease, hydration may be all that is necessary, without any diet restriction. This can be achieved with oral rehydration therapy to supplement a regular diet. Packets of dry rehydration powder to be mixed with water are available from pharmacies, either prior to travel or at the destination. If this is not available, parents can be instructed on how to make oral rehydration solution (Table 45–5) or to use a sports drink such as Gatorade as a suitable alternative in older children and toddlers. The breast-fed infant should continue to breast-feed, in addition to receiving oral rehydration therapy.

The vomiting child is at greater risk of dehydration, so aggressive rehydration is crucial. Parents should be reassured that some fluid will be absorbed even if vomiting is ongoing. This is best achieved with small amounts of fluid, given often to prevent further vomiting. The antimotility agent loperamide, which is often used in adults to minimize symptom duration, is not advised for children because of the risk of adverse events such as toxic megacolon, ileus, extrapyramidal signs, hallucinations, and coma. Bismuth subsalicylate decreases the number of unformed stools in adults. Its routine use is not recommended in pediatrics, as aspirin is contraindicated in children younger than 18 years because of the risk of Reye syndrome, and dosing of bismuth has not been established for children.

For children with signs and symptoms of bacterial gastroenteritis, such as fever or blood in the stool, empiric antibiotic therapy should be considered. The drug of choice in children is azithromycin (10 mg/kg orally once a day for 3 days). It is available in a powdered form that can be reconstituted and stored without refrigeration. It is a good choice because of the growing resistance of many gastroenteritis-causing bacteria to ciprofloxacin. There are no pediatric trials of empiric azithromycin, so the dosing recommendations are based on pharmacokinetic data and studies involving the treatment of diarrhea in Africa and Thailand. Ciprofloxacin is currently not recommended for treatment of traveler’s diarrhea in children, though it is used for treatment in adults.

Trimethoprim-sulfamethoxazole (TMP-SMX) has been used to treat traveler’s diarrhea in children but is no longer recommended because of increasing antibiotic resistance. Rifaximin, a nonabsorbable derivative of rifamycin, is effective in treating ETEC and other noninvasive enteropathogens. Since it is not absorbed, high concentrations are achieved in the intestinal lumen and it has a good safety profile. It is licensed for patients 12 years of age and older at a treatment dose of 200 mg three times a day for 3 days.

The use of prophylactic antibiotics is not recommended because of the risk of adverse events to prevent a disease of limited morbidity, as well as the effect of potential for emergence of antibiotic resistance. Rifaximin, however, is showing promise in adult studies as a chemoprophylactic agent, but it is expensive and requires further study in pediatrics. Probiotics are of unproven benefit for the prevention of traveler’s diarrhea, with contradictory reports of efficacy in adult studies.

**MALARIA PROPHYLAXIS & PREVENTION**  
*(SEE ALSO CHAPTER 43)*

Malaria is the most common preventable infectious cause of death among travelers, and a common cause of fever in the returned traveler. Children comprise 20% of imported cases of malaria. It is largely a preventable disease in travelers through personal protective measures and chemoprophylaxis. However, no method is 100% protective. The risk of acquiring malaria varies with the season, climate, altitude, number of mosquito bites, and destination, with the highest risk in Oceania, Africa, the Indian subcontinent, and the Amazon.

---

#### Prevention of Mosquito Bites

Malaria is transmitted via the night-biting *Anopheles* mosquitoes. Mosquito bites are avoided by staying in well-screened and air-conditioned rooms from dusk until dawn, wearing clothing covering arms and legs, and avoiding scented soaps, shampoos, and perfumes. Mosquito nets are highly effective and can be used over beds, cribs, playpens, car seats, and strollers. Repellants containing 25%–50% DEET are also recommended, as this concentration confers 5–8 hours of protection. When used appropriately, DEET is safe for infants and children older than 2 months. It should not be applied to children’s hands, mouth, or near the eyes, and is best washed off upon returning indoors. There have
been case reports of seizures and toxic encephalopathy with use of DEET, but these cases occurred with misapplication. Icaridin (formerly picaridin) is an alternative to DEET available in many countries. A concentration of 20% icaridin is as effective as DEET-containing products. It lacks the corrosiveness and greasy texture of DEET, and has been advised as safe for use in children by the American Academy of Pediatrics. However, because it is relatively new, it lacks the safety profile of DEET, especially for children. PMD is a plant-based repellant derived from lemon eucalyptus, and at a 30% concentration is of equal efficacy to DEET. It may be used on children older than 6 months. It is considered safe if directions are followed and has been advocated for use by the Centers for Disease Control. Clothing and bed nets may be sprayed with insecticides such as permethrin, which confers protection for 2–6 weeks, even with regular washing. Further studies are needed to establish its safety profile in children. The combination of DEET every 8–12 hours and permethrin on clothing is over 99% effective in prevention of mosquito bites.

## Chemoprophylaxis

Prophylactic medications suppress malaria by killing asexual blood stages of the parasite before they cause disease, so protective levels of medication must be present in the blood before developing parasites are released from the liver. Therefore, it is necessary to start prophylaxis before the first possible exposure and to continue it for a sufficient period after return to a safe area.

The choice of antimalarial depends on the age of the child, resistance patterns, restrictions on the agent of choice, the child’s ability to swallow tablets, the frequency of dosing, cost, availability of medication, and access to a compounding pharmacy for adequate dispensing of medication. For most children, once-weekly mefloquine is preferable and is approved for use in children of any age. Atovaquone/proguanil is available in pediatric dosing, although only in tablet formulation. It is currently approved in most countries for children weighing greater than 5 kg. Doxycycline is another alternative but should be used only in children 8 years or older because of the risk of teeth staining. Chloroquine is the drug of choice in areas of chloroquine sensitivity (Mexico, Hispaniola, Central America, west and north of the Panama Canal, and parts of North Africa, the Middle East, and China). Pediatric and adult dosing, side effects, and other information about malaria chemoprophylaxis are in Table 45–6.

Antimalarial medications (with the exception of atovaquone/proguanil) are bitter, so it may be necessary to grind the medication into a very sweet food, such as chocolate syrup or sweetened condensed milk. Infants may need to have their medication prepared by a compounding pharmacy, where the appropriate dose can be placed in a gelatin capsule, which can then be opened by the caregiver and mixed into food or liquid.

## VISITS TO FRIENDS & RELATIVES (VFR) IN HIGH-RISK AREAS

Individuals who return to their home country are at the highest risk of travel-related infectious diseases. Sixty percent of malaria cases and over 75% of typhoid cases occur in these travelers, and VFR children are at highest risk of hepatitis A. The reasons for this include the following:

- Longer stays and increased likelihood of pregnancy or young age in the traveler
- Travel to remote rural areas
- Intimate contact with the local population
- Decreased likelihood of seeking (or following) pretravel advice because of familiarity with their home country
- Assumed immunity to infections
- Sociocultural barriers—for example, language barriers, prohibitive cost of vaccines, and medications if lower socioeconomic status, belief systems of illness
- Eating and sleeping in local households, where hygiene may be suboptimal
- Use of high-risk forms of transportation

Thus, certain issues need to be emphasized when discussing travel for VFRs. Given the risk of waterborne infections, visiting families should boil water and milk if other safe drinking water is expensive; consume only piping hot foods and beverages; and follow proper hand-washing techniques at all times. Vaccination recommendations and malaria prophylaxis are of greater importance in VFRs. Similarly, VFRs provide greater opportunity for contracting vaccine-preventable diseases, such as typhoid, rabies, yellow fever, and meningococcal infection. They are associated with a higher risk of exposure to people with tuberculosis, so for this reason PPD testing is recommended after return from travel.
Table 45–6. Malaria prophylaxis.

Primaquine presumptive anti-relapse therapy is administered for 14 d after the traveler has left a malarious area. When chloroquine, doxycycline, or mefloquine is used for prophylaxis, primaquine is usually taken during the last 2 wk of postexposure prophylaxis, but may be taken immediately after those medications are completed. When atovaquone/proguanil is used for prophylaxis, primaquine may be taken either during the final 7 d of atovaquone/proguanil and then for an additional 7 d, or for 14 d after atovaquone/proguanil is completed.

Indicated for persons who have had prolonged exposure to *P. vivax* and *P. ovale* or both (e.g., missionaries or peace corps volunteers). All persons who take primaquine should have a documented normal G6PD (glucose-6-phosphate dehydrogenase) level prior to starting this medication. Contraindicated in persons with G6PD deficiency. Also contraindicated during pregnancy and lactation unless the breast-fed infant has a documented normal G6PD level. Also an option for prophylaxis in special circumstances.
HIV & SEXUALLY TRANSMITTED DISEASES
(SEE ALSO CHAPTER 41)

Adolescent travelers may partake in high-risk activities while traveling, putting them at risk of human immunodeficiency virus (HIV) and other sexually transmitted diseases (STDs). The adolescent traveler should be counseled about the risks of STDs and abstinence or safe sexual practices. Bringing a supply of latex condoms may be appropriate along with instruction on their proper use. They should be advised that HIV and STDs can also be contracted via oral sex and in nonsexual activities such as intravenous drug use. They should avoid tattoos, pedicures, and dental care while traveling. There may be a risk of HIV and other virus transmission through injections and blood transfusion, as many developing countries do not have adequate blood banking and transfusion protocols. In fact, 10%–20% of countries have inadequate screening.

Antiretroviral therapy is recommended if there is exposure to a known HIV-positive contact, and may be considered if the source is unknown. The usual recommended regimens are outlined in Chapter 41.

Further information on HIV can be found in Chapter 41.

FEVER IN THE RETURNED TRAVELER

More than half of travelers to the developing world experience a health-related travel problem during their trip; 8% require medical attention on return. The majority will develop common medical problems, such as upper respiratory tract infections, pneumonia, urinary tract infections, and otitis media, with the remainder developing travel-related infections. The most common of these diseases are malaria (21%), acute traveler’s diarrhea (15%), dengue fever (6%), and typhoid/enteric fever (2%). Children who travel with caretakers visiting friends and relatives are at greatest risk. New pathogens and the changing epidemiology of some infectious diseases pose new risks to travelers—such as avian influenza, multidrug-resistant TB, chikungunya virus, and leishmaniasis.

Symptomatic returning travelers should be urgently and thoroughly evaluated for travel-related illness to prevent serious life-threatening disease and transmission to close contacts. The initial evaluation should include questions directed toward the travel itinerary, with dates of arrival and departure, specific activities, rural versus urban location, and accommodations. Specific information should be obtained regarding fresh water contact (eg., schistosomiasis, leprospirosis in some areas), sexual contacts, animal exposures, activities or hobbies, ill person contacts, and sources of food and water. A complete medication and vaccination history should be sought. It should be noted that despite malaria chemoprophylaxis and protection against mosquitoes, no regimen is 100% protective. A thorough physical examination should include dermatologic examination, eye examination for scleral icterus, conjunctival injection or petechiae, and evaluation for hepatosplenomegaly or lymphadenopathy. Routine laboratory evaluation includes a complete blood count, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), serum chemistry, liver enzyme profile, and urinalysis. The laboratory evaluation should also focus on diseases that are life-threatening, with thick and thin smears for malaria (ideally three that are 12 hours apart), and blood cultures for typhoid fever. Specific testing should be done as directed by findings on history, physical examination, and preliminary laboratory test findings (Table 45–7). It may be necessary to seek the opinion of individuals with experience in international travel medicine, if available.

Fever is the most common complaint in a child who becomes ill after international travel. The most common travel-related infectious causes of fever are outlined as follows.

Malaria

Malaria is a medical emergency, as a child infected with *Plasmodium falciparum* may progress from relatively minor symptoms to death in less than 24 hours. A child with malaria presents with paroxysmal high fevers, sweats, rigors, headaches, and malaise. The presence of nausea, vomiting, and abdominal pain in pediatric malaria may mimic acute gastroenteritis. Patients infected with *P falciparum* usually present within 2 months of exposure, whereas patients with *Plasmodium vivax* and *Plasmodium ovale* can present months to years after infection.

A more detailed description of the symptoms of malaria, diagnosis, and treatment is presented in Chapter 43.

Dengue Fever

Dengue fever is an important tropical disease frequently encountered in travelers. The incubation period is 3–14 days; therefore, dengue should be considered for a febrile illness within the first 2 weeks after return from travel. It is acquired more commonly during urban travel in the
daylight hours because of the biting preference of the vector *Aedes aegypti* mosquito. The classic presentation is high fever, retro-orbital headache, myalgias, arthralgias, diffuse blanching maculopapular, or petechial rash. It is possible for children to present with fever and irritability alone. Further information about dengue fever is presented in Chapter 40.

### Typhoid Fever

Typhoid fever, which is a relatively common cause of fever in children after travel, is caused by *Salmonella typhi*. A common presentation of typhoid fever is with fever, headache, abdominal pain, and initial diarrhea followed by constipation. Enteric fever has a similar presentation and is caused by other serovars of *Salmonella*. A person with typhoid fever usually appears toxic, and on examination may have hepatosplenomegaly and rarely rose spots. Typhoid fever is discussed in Chapter 42.

Information about other diseases sometimes occurring in the returned traveler is provided in Table 45–8 and Chapter 43.

General References

Laboratory tests provide valuable information necessary to evaluate a patient’s condition and to monitor recommended treatment. Chemistry and hematology test results are compared with those of healthy individuals or those undergoing similar therapeutic treatment to determine clinical status and progress. In the past, the term *normal ranges* relayed some ambiguity because statistically, the term *normal* also implied a specific (Gaussian or normal) distribution and epidemiologically it implied the state of the majority, which is not necessarily the desirable or targeted population. This is most apparent in cholesterol levels, where values greater than 200 mg/dL are common, but not desirable. Use of the term *reference range* or *reference interval* is therefore recommended by the International Federation of Clinical Chemistry (IFCC) and the Clinical and Laboratory Standards Institute (CLSI, formerly the National Committee for Clinical Laboratory Standards [NCCLS]) to indicate that the values relate to a reference population and clinical condition.

Reference ranges are established for a specific age (eg, alpha-fetoprotein), sex, and sexual maturity (eg, luteinizing hormone and testosterone); they are also defined for a specific pharmacologic status (eg, taking cyclosporine), dietary restrictions (eg, phenylalanine), and stimulation protocol (eg, growth hormone). Similarly, diurnal variation is a factor (eg, cortisol), as is degree of obesity (eg, insulin). Some reference ranges are particularly meaningful when combined with other results (eg, parathyroid hormone and calcium), or when an entire set of analytes is evaluated (eg, lipid profile: triglyceride, cholesterol, high-density lipoprotein, and low-density lipoprotein).

Laboratory tests are becoming more specific and measure much lower concentrations than ever before. Therefore, reference ranges should reflect the analytical procedure as well as reagents and instrumentation used for a specific analysis. As test methodology continues to evolve, reference ranges are modified and updated.

**CHALLENGES IN DETERMINING & INTERPRETING PEDIATRIC REFERENCE INTERVALS**

The pediatric environment is particularly challenging for the determination of reference intervals since growth and developmental stages do not have a distinct and finite boundary by which test results can be tabulated. Reference ranges may overlap and, in many cases, complicate diagnosis and treatment. Collection and allocation of test results by age for the purpose of establishing a reference range is a convenient and manageable way to report them, but caution is needed in their interpretation and clinical correlation.

A particular difficulty lies in establishing reference ranges for analytes whose levels are changed under scheduled stimulation conditions. The common glucose tolerance test is such an example, but more complex endocrinology tests (eg, stimulation by clonidine and cosyntropin) require skill and extensive experience to interpret. Reference ranges for these serial tests are established over a long period of time and are not easily transferable between test methodologies. Changing analytical technologies add a new dimension to the challenges of establishing pediatric reference ranges.

**GUIDELINES FOR USE OF DATA IN A REFERENCE RANGE STUDY**

The College of American Pathologists provides guidelines for the adoption of reference ranges used in hospitals and commercial clinical laboratories. It recognizes the enormous task of establishing a laboratory’s own reference ranges, and
The establishment of reference intervals is based on a statistical distribution of test results obtained from a representative population. The CLSI recommendation for data collection and statistical analysis provides guidelines for managing the data. For clinicians, it is not important that they can reproduce the calculation. It is far more critical to understand the benefits and restrictions provided by the described statistical approaches and to evaluate patient results with these limitations in mind.

In reviewing the statistics, 95% of all results will be inherently included in the reference range. Note that 5% of that population will have “abnormal” results, when in fact they are “healthy” and an integral part of the reference group study. Similarly, an equivalent 5% of the “ill” population will have laboratory results within the reference range. These are inherent features of the statistical computation. Taking that analysis one step further, the probability of a healthy patient having a test result within a calculated reference range is

\[ P = 0.95 \]

When multiple tests or panels of tests are used, the combined probability of all the test results falling in their respective reference ranges drops dramatically. For example, the probability of all results from 10 tests in the complete metabolic panel being in the reference range is

\[ P = (0.95)^{10} = 0.60 \]

Therefore, about one-third of healthy patients will have one test result in the panel that is outside the reference range.

A. Parametric Method of Computation

The parametric method of establishing reference intervals is simple, though not always representative, since it is based on the assumption that the data have a Gaussian distribution. A mean (x) and standard deviation (s) are calculated; test results of 95% of that specific population will fall within the mean ±1.96s, as shown in Figure 46-1.

Where the distribution is not Gaussian, a mathematical manipulation of the values (eg, plotting the log of the value, instead of the value itself) may give a Gaussian distribution. The mean and standard deviation are then converted back to give a usable reference range.

B. Nonparametric Method of Computation

The nonparametric method of establishing reference ranges is currently recommended by CLSI, since it defines outliers as those in the extreme 2.5 percentile of the upper and lower limits of data, respectively. The number of data points

---

**STATISTICAL COMPUTATION OF REFERENCE INTERVALS**

The establishment of reference intervals is based on a statistical distribution of test results obtained from a representative population. The CLSI recommendation for data collection and statistical analysis provides guidelines for managing the data. For clinicians, it is not important that they can reproduce the calculation. It is far more critical to understand the benefits and restrictions provided by the described statistical approaches and to evaluate patient results with these limitations in mind.

In reviewing the statistics, 95% of all results will be inherently included in the reference range. Note that 5% of that population will have “abnormal” results, when in fact they are “healthy” and an integral part of the reference group study. Similarly, an equivalent 5% of the “ill” population will have laboratory results within the reference range. These are inherent features of the statistical computation. Taking that analysis one step further, the probability of a healthy patient having a test result within a calculated reference range is

\[ P = 0.95 \]

When multiple tests or panels of tests are used, the combined probability of all the test results falling in their respective reference ranges drops dramatically. For example, the probability of all results from 10 tests in the complete metabolic panel being in the reference range is

\[ P = (0.95)^{10} = 0.60 \]

Therefore, about one-third of healthy patients will have one test result in the panel that is outside the reference range.

A. Parametric Method of Computation

The parametric method of establishing reference intervals is simple, though not always representative, since it is based on the assumption that the data have a Gaussian distribution. A mean (x) and standard deviation (s) are calculated; test results of 95% of that specific population will fall within the mean ±1.96s, as shown in Figure 46-1.

Where the distribution is not Gaussian, a mathematical manipulation of the values (eg, plotting the log of the value, instead of the value itself) may give a Gaussian distribution. The mean and standard deviation are then converted back to give a usable reference range.

B. Nonparametric Method of Computation

The nonparametric method of establishing reference ranges is currently recommended by CLSI, since it defines outliers as those in the extreme 2.5 percentile of the upper and lower limits of data, respectively. The number of data points

---

**STATISTICAL COMPUTATION OF REFERENCE INTERVALS**

It is far more critical to understand the benefits and restrictions provided by the described statistical approaches and to evaluate patient results with these limitations in mind.

In reviewing the statistics, 95% of all results will be inherently included in the reference range. Note that 5% of that population will have “abnormal” results, when in fact they are “healthy” and an integral part of the reference group study. Similarly, an equivalent 5% of the “ill” population will have laboratory results within the reference range. These are inherent features of the statistical computation. Taking that analysis one step further, the probability of a healthy patient having a test result within a calculated reference range is

\[ P = 0.95 \]

When multiple tests or panels of tests are used, the combined probability of all the test results falling in their respective reference ranges drops dramatically. For example, the probability of all results from 10 tests in the complete metabolic panel being in the reference range is

\[ P = (0.95)^{10} = 0.60 \]

Therefore, about one-third of healthy patients will have one test result in the panel that is outside the reference range.

A. Parametric Method of Computation

The parametric method of establishing reference intervals is simple, though not always representative, since it is based on the assumption that the data have a Gaussian distribution. A mean (x) and standard deviation (s) are calculated; test results of 95% of that specific population will fall within the mean ±1.96s, as shown in Figure 46-1.

Where the distribution is not Gaussian, a mathematical manipulation of the values (eg, plotting the log of the value, instead of the value itself) may give a Gaussian distribution. The mean and standard deviation are then converted back to give a usable reference range.

B. Nonparametric Method of Computation

The nonparametric method of establishing reference ranges is currently recommended by CLSI, since it defines outliers as those in the extreme 2.5 percentile of the upper and lower limits of data, respectively. The number of data points
excluded at the limits depends on the skew of the curve, and so the computation accommodates a non-Gaussian distribution. A histogram depicting the non-Gaussian distribution of data from a free thyroxine reference range study conducted at Children’s Hospital in Denver is shown in Figure 46–2.

WHY REFERENCE INTERVALS VARY

Recent modifications to reference ranges are due to the introduction of new and improved analytical procedures, advanced automated instrumentation, and standardization of reagents and reference materials. Reference ranges are also affected by preanalytical variations that can occur during sample collection, processing, and storage.

Preanalytical variations of biological origin can occur when specimens are drawn in the morning versus in the evening, or from hospitalized recumbent patients versus ambulatory outpatients. Variations also may be caused by metabolic and hemodynamic factors. Preanalytical factors may be a product of the socioeconomic environment or ethnic background (eg, genetic or dietary).

Analytical variations are caused by differences in analytical measurements and depend on the analytical tools as well as an inherent variability in obtaining a quantitative value. Furthermore, scientific progress is constantly introducing new reagents, instruments, and improved testing procedures to the clinical laboratory, and each tool adds an element of variability between tests.

1. Antigen-antibody reactions have revolutionized clinical chemistry, but have also added a degree of variability because biologically derived reagents have different specificity and sensitivity. In addition to the targeted analyte, some of its metabolites are also measured, and these may or may not be biologically active.

2. Reference materials continue to be reviewed and evaluated by organizations such as the World Health Organization and the National Institute for Standards and Technology. A new standard was recently established for troponin I, and reference ranges were modified to reflect the new standard.

3. Analytical instrumentation with advanced electronics and robotics has improved accuracy of results and increased throughput. However, they have added an element of variability between instruments from different manufacturers.

4. Analytical detection methods have also made big strides as they have expanded from simple ultraviolet-visible spectrophotometry to fluorescence, nephelometry, radioimmunoassay, and chemiluminescence. For example, the third-generation thyroid-stimulating hormone assays can now measure concentrations as low as 0.001 μIU/mL; the reference range was recently modified to reflect the improved sensitivity of the assay.

SENSITIVITY & SPECIFICITY

Despite its statistical derivation, a reference interval does not necessarily provide a finite and clear-cut guideline as to whether a patient has a disease. There will always be a segment of the population with test values that fall within the reference interval, but clinical manifestations that indicate disease is present. Similarly, a segment of the population will have test values outside the reference interval, but no clinical signs of disease. The ability of a test and corresponding reference interval to detect individuals with disease is defined by the diagnostic sensitivity of the test. Similarly, the ability of a test to detect individuals without disease is described by the diagnostic specificity. These characteristics are governed by the analytical quality of the test as well as the numerical parameters (reference interval) that define the presence of disease. The tolerance level for the desired sensitivity and specificity of a test requires significant input from clinicians.

Generally, specificity increases as sensitivity decreases. A typical reference range frequency distribution, shown in Figure 46–3 (solid line), provides information on the test results of a number of healthy subjects, or individuals without the disease. A second curve (dashed line) shows test results for individuals with the disease. As with most tests, there is an overlap area. A patient with a test result of 1 is likely healthy, and the result indicates a true negative (TN) for the presence of disease. A patient with a test result of 9 is likely to have the disease and the test result is a true positive (TP). There is a small, but significant, population with a test result of 2–5 in whom the test is not 100% conclusive. A statistical analysis may determine the most likely cutoff for healthy individuals, but the clinically acceptable cutoff depends on the test as well as clinical correlation. Where the treatment is aggressive and has serious side effects, a clinician may choose to err on the side of caution and hold treatment for anyone with a test value of less than 6.

If cutoff values for the reference interval are such that a test result indicates that a healthy patient has the disease, the result is a false positive (FP). Conversely, if a test result indicates that a patient is well when in fact he or she has the disease, the result is a false negative (FN). To define the ability of the test and reference interval to identify a disease state, the diagnostic sensitivity and specificity are measured.

\[
\text{Diagnostic sensitivity} = \frac{\text{TP}}{\text{TP} + \text{FN}}
\]

\[
\text{Diagnostic specificity} = \frac{\text{TN}}{\text{TN} + \text{FP}}
\]

In the example shown in Figure 46–3, a reference interval of 0.5–3 will provide more TN results and minimize FP results. Alternatively, a reference interval of 0.5–4 will increase the rate of FN. Thus, an increase in sensitivity leads to a decrease in specificity. A medical condition that requires aggressive treatment may necessitate a test and corresponding reference interval with a high sensitivity, which is a measure of the TP rate. This is accomplished at the expense of lowering specificity.

A reference interval is a statistical representation of test results from a finite population, but it is by no means inclusive of every member of the group. It is merely one component in the measure of a patient’s status to be viewed in relation to the sensitivity and specificity of the test.

Clinical laboratory data are frequently interpreted using a dynamic approach in which each value is compared with another. In this case, time series analysis of relative values may provide more important information than comparison against a strict reference range. Examples include the evaluation of enzyme activity over time and various stimulation studies for endocrine assessment. Drug monitoring also is a dynamic process.

PEDIATRIC REFERENCE INTERVALS

The establishment of reference ranges is a complex process. Assumptions are made in the management of data processes, regardless of whether “healthy” individuals or hospital patients are used for the accumulation of test results. Analytical instrument manufacturers conduct large studies to identify reference intervals for each specific analyte, and pediatric values have always been the most challenging. Some of the manufacturers’ recommended reference intervals are listed in Table 46–1 for general chemistry, Table 46–2 for endocrinology, and Table 46–3 for hematology. The interpretation of chemistry and hematology laboratory results is equally complex and forms a continuous challenge for physicians and the medical community at large.

Immunodeficiency (Cont.): phagocyte disorders, 1047–1048 primary. See Primary immunodeficiencies purine nucleoside phosphorylase deficiency, 1047 selective immunoglobulin deficiencies, 1039, 1042 severe combined immunodeficiency diseases (SCIDs), 1040, 1042–1044 transcobalamin 2 deficiency, 1052 transient hypogammaglobulinemia of infancy, 1039, 1041–1042 Turner syndrome, 1052 22q11.2 deletion syndrome, 1045–1046 WHIM syndrome, 1051 Wiskott-Aldrich syndrome, 1044–1045 X-linked agammaglobulinemia, 1038, 1040 X-linked lymphoproliferative syndrome, 1050–1051 Immunodeficiency, centromeric instability, facial anomalies (ICF) syndrome, 1052 Immunoglobulin, 303–304 anti-Rh(D), in idiopathic thrombocytopenic purpura (ITP) management, 966 deficiencies evaluation, 1035–1036, 1037t selective, 1039, 1042 hyper IgM syndrome, 1040–1041 Ig heavy-chain gene deletions, 1039t IgA deficiency, 1039, 1042 nephropathy, 758t, 759 intravenous, in idiopathic thrombocytopenic purpura (ITP) management, 965 normal values, age-related, 1037t tetanus, 284–285, 284t, 1310–1311 Immunologic evaluation, in acute otitis media (AOM) prevention, 508 Immunologic function, laboratory evaluation, 754–755 Immunomodulator in inflammatory bowel disease (IBD) management, 693 in myasthenic syndrome management, 855 Immunosuppression, cardiac transplantation and, 637 Immunotherapy in allergic rhinoconjunctivitis management, 1189–1190 in asthma management, 1183 Impaction, tooth, 498 Impaired contractility, 403 Imperforate anus, 672–673 Impetigo, 435 bullous, 435 group A streptococcal infections and, 1284 Imprinting, 1147 Independent assortment, defined, 1142 Indinavir, 1278t Indinance CNS degenerative disorders of, 818, 819–823 idiopathic hypercalcemia of, 1077 red cell volume in, 939, 940f transient hypogammaglobulinemia of, 1039, 1041–1042 Infant apparent life-threatening events (ALTEs), 583–587, 584t assessment and management of the acutely ill patient, 334–340 colic in, 96 concept of death, 1030t congenital syphilis in, 1345, 1346 disorders in. See specific disorders dysmorphology in, evaluation, 1150–1151, 1152f feeding disorders in, 97–98 formulas for. See Formula narcissistic possessiveness of, 88 newborn, 9–74. See also Newborn nutrition for, 311, 313–314, 316–318, 319t, 320t breast feeding, 311, 313–314, 316–318, 319t, 320t formula additives, 320–321, 320t soy protein formulas, 320 special formulas, 321 oral examination in, 495–497, 495f–497t cleft lip, 496–497 cleft palate, 496–497, 497t freena, 496, 496f soft tissue variations, 497 sucking pads, 495 teeth, 495 oral health in, 491 perinatal exposure to HIV infection, 1272t, 1273–1274. See also HIV infection preterm, 40–50. See also Preterm infants sepsis in, antimicrobial agents for, 1217 skin disorders in, 432–446. See also specific disorders teeth eruption in, 497–498 term, early, 51f vomiting and encephalopathy in, inborn errors of metabolism and, 1107, 1108t Infantile botulism, 859t Infantile cortical hyperostosis, 882–883 Infantile Gaucher disease, 821t Infantile masturbation/gratification movements, 792t Infantile neuropathy, 859t Infantile spasms, described, 787t Infection. See also Eyelid, infections; specific types, eg, Bacterial infections bacterial, 1283–1344 CNS, 835–838, 836t head injury and, 347–349 eyelid, 461, 461f nasal, 521 neonatal thrombocytopenia associated with, 967
INDEX
Intracranial hypertension, treatment (Cont.): algorithm for, 412
mechanical therapies, 411
medical therapies, 411
Intracranial pressure (ICP), increased, management, 411
Intractable pain, palliative care for, 1028
Intraductal papilloma, 136
Intrahepatic cholestasis, 695–703, 696
clinical findings, 696, 696a
complicating, treatment, 698
outcomes, 698
diagnostic studies, 696
complicating, treatment, 698
Intrahepatic portal hypertension, 724
Intrahepatic cholestasis, 695–703, 696
inborn errors of metabolism and, 697–701
Intrahepatic cholestasis due to, 698
Iodine, 312
Intrinsic anticoagulants, deficiencies, 978
Intabulation endotracheal, in acute respiratory failure, 390–391, 391a
Intussusception, 665–666
rotavirus vaccination and, 281–282
In utero cytomegalovirus (CMV) infections, 1250–1251
Inversion, chromosomal, 1137, 1137a
Involuntary mental health “hold,” 193–194
I/O access (intraosseous access), 338–339, 338a
Iodide, in hyperthyroidism management, 1069
Iodine, 312
IOP (intracranial pressure), 136
Intrapulmonary shunt fraction, 405
Intrapulmonary shunt, in acute respiratory failure, 388
Intrapulmonary shunt fraction, 405
Intrarheumatic airways disorders acquired, 550
foreign body aspiration, 550
genital, 548–550
bronchogenic cysts, 549–550
malacia of Airways, 548–549
vascular rings and slings, 549
Intraterine devices (IUDs), 154
Intraterine growth curves, 11f, 12
Intraterine growth restriction (IUGR) infants, hypoglycemia in, 27
multiple births and, 34
Intraterine infections, in newborns, 62–63, 64a
Intraterine systems (IUS), 154
Intravaginal ring, 153
Intravenous access, in shock, 338–339
Intravenous (IV) calcium therapy, in hypoalbuminemia management, 73–74
Intravenous immunoglobulin (IVIG), in idiopathic thrombocytopenic purpura (ITP) management, 965
Intraventricular hemorrhage, in preterm infants, 47–48, 47a
clinical findings, 48
diagnosis, 48
general considerations, 47–48, 47a
pathogenesis, 47–48, 47a
prognosis, 48
treatment, 48
Intrauterine growth restriction (IUGR), 12
Intrauterine infections, in newborns, 301–302
treatment, 1427–1429
Jaundice
breast milk, 706
breast-feeding, 317
neonatal, 19–27. See also Neonatal jaundice
Physiologic, 19–20, 20a
prolonged neonatal cholestatic, 695, 696
JC (Joint Commission), 3
See Japanese encephalitis
JIA. See Juvenile idiopathic arthritis

Joint infections of, 874–878
Joint Commission (JC), 3
Joint fluid, analysis, 928, 928a
Jones criteria, in rheumatic fever, diagnosis, 626, 627
Jumper’s knee, sports-related, 912
Junctional premature beats, 641
Juvenile absence epilepsy, described, 788, 789a
Juvenile diabetes. See Diabetes mellitus, type 1
Juvenile idiopathic arthritis (JIA), 927–930, 928a
clinical findings, 927–928, 928a
described, 927
Jumper’s knee, sports-related, 912
Juvenile myelomonocytic leukemia (JMML), 996t, 997
Juvenile myoclonic epilepsy, described, 789, 790
Juvenile nephrophihsis, 756
Juvenile papillomatosis, 136
Juvenile parotitis, recurrent, 532
Juvenile polyposis syndrome, 677a
Juvenile polyps, 676, 676f, 677
Juvenile recurrent parotitis, 532
Juvenile rheumatoid arthritis, red rash in, 1231a
K
K chain deficiency, 1039
Kabuki syndrome, 1167
Kala-azar, 1356
Kaposiform hemangioendotheliomas, thrombocytopenia associated with, 967
Karyotype, normal male and female, 1135, 1135a
Kasabach-Merritt syndrome, 967
Kawasaki disease, 628–629, 628a
long-term management, 629
red rash in, 1231a
Keloid, 442
Keratitis, viral, 474–475
Keratoconjunctivitis, 1244
epidemic, 1233
treatment, 1246
Keratolytic agents, topical, for acne, 433, 434t
Keratitis, 442
Keratoconus, 19, 23
Ketamine
in ICU, 420
procedural, 356
Ketoacidosis, diabetic, management, 1104–1105
Ketoaciduria, branched-chain, 1118
Ketogenic diet, in seizure management, 794–796
Ketoacidosis, diabetic, management, 1104–1105
Ketamine
Kernicterus, 19, 23
Keratosis pilaris, 442
Keratolytic agents, topical, for acne, 433, 434t
Knee injuries, sports-related, 912–915
collateral ligament injuries
lateral, 913–914
medial, 913–914
cruciate ligament injuries
anterior, 914
posterior, 914–915
meniscal injuries, 913
Osgood-Schlatter disease, 912
patellar tendonitis, 912
patellofemoral overuse syndrome, 912
Sinding-Larsen-Johansen disease, 913
Knee pain
anterior, sports-related, 912–913
posterior, sports-related, 913
Knee sprains, 872
Knick-knee, 869
Köhler bone disease, 878t
Krabbe disease, clinical and laboratory features, 1127t
Krabbe leukodystrophy, 819t
L
LABAs (long-acting bronchodilators), in asthma management, 1182
Labetalol, for acute hypertensive emergencies, 768, 769t
Lalisch sucking tubercle, 531
Labyrinthitis, acute otitis media (AOM)
and, 511
Laceration, ocular, 455
f,
456–457, 457
Lactase deficiency, 689
Lacosamide, in seizure management, 795t
Ladder, described, 1201
Latex, described, 1201
Latex allergy, 1201–1202
clinical findings, 1201–1202
complications, 1202
general considerations, 1201
laboratory findings, 1201–1202
prognosis, 1202
symptoms and signs, 1201
 treatment, 1202
Lavage
antral, for recurrent rhinosinusitis, 520
in poisoning treatment, 361
LD₅₀ of drug, 357
Lead
poisoning, treatment, 377–378
risk questionnaire, elements, 258, 258t
screening, 258, 258t
Leapfrog, 2
Leffleroid, in juvenile idiopathic arthritis (JIA) management, 929
Left coronary artery, anomalous origin, 615–616
Legg-Calvé-Perthes disease, 878–879, 878t
Legionella infection, 1339–1340
Leigh disease, 821t
Leigh subacute necrotizing encephalomyelopathy, 1163
Leishmaniasis spp.
L braziliensis, parasitic infections due to, 1356t
L donovani, parasitic infections due to, 1356t
L mexicana, parasitic infections due to, 1356t
L tropica, parasitic infections due to, 1356t
Length for age
boys, birth to age 24 months, 78f, 79f
girls, birth to age 24 months, 77f
Lennox-Gastaut syndrome, 788t
Lens
dislocated, 476–477
disorders, 475–477
Leptin, in anorexia nervosa, 172
Leptospirosis, 1349–1350
Leptospirosis, 1349–1350
red rash in, 1231t
in returned traveler, 1437t
Lesion
brachial plexus, 923–924
breast, 136–137, 136t
cardiac, cyanotic, pulmonary blood flow in, alternatives, 594t
skin, congenital, candidiasis and, 1387, 1389
vascular, orthopedic-related, 878–879, 878t
Leukemia
lymphoblastic, acute, 990–993. See also
Acute lymphoblastic leukemia
myelogenous, chronic, 996–997, 999t
myeloid, acute, 993–996, 994t. See also
